Composites of tungsten carbide (WC) and stainless steel (SS) have been produced through an innovative powder coating technique via a novel sputtering process. These composites showed remarkable mechanical properties after vacuum sintering, in spite of significant amounts of brittle eta-phase, (M,W)\textsubscript{6}C \cite{1}. The formation of eta-phase is almost inevitable, because it is thermodynamically favoured in the system WC-SS for stoichiometric C and accelerated in the SS coated WC particles, due to the reduced diffusion distances between WC and SS and the nanocrystalline character of the metallic coating \cite{2}. Surprisingly, the mechanical properties are not seriously affected by the eta-phase. In fact, relatively tough and harder materials have been obtained compared to similar compositions of WC-Co. In order to understand the microscopic reason for the mechanical strength, in-depth structural analysis of grain boundaries and interfaces was performed by electron microscopy.

Composites prepared from WC powders that were coated with \textasciitilde 10 wt.% of SS and subsequently sintered in vacuum atmosphere at 1400°C, during 2 h at 20 Pa, were analyzed. High resolution scanning and transmission electron microscopy, using a Hitachi SU 70 SEM and a JEOL 2200FS TEM, respectively, were applied in combination with energy dispersive X-ray (EDX) elemental mapping in order to study the phase and elemental composition of the sample. Preliminary results corroborate the existence of three phases in the sintered sample; WC matrix phase, Fe rich binder (Fe\textsubscript{2.3}Cr\textsubscript{0.6}Ni\textsubscript{0.3})(Cr\textsubscript{0.6}W\textsubscript{2.8})C (Figure 1).

Thin layers of Fe rich binder phase between the WC and the (M,W)\textsubscript{6}C grains could be detected by TEM (Figure 2). The binder phase spreads as well on the WC as on the (M,W)\textsubscript{6}C surfaces with excellent interpenetration between their
junctions as illustrated in Figure 2, where a continuous thin layer of Fe rich phase, less than 4 nm, can be clearly observed at the interface of those carbide phases. The existence of ductile films along grain boundaries and phase interfaces are responsible for the good mechanical properties, namely the high toughness attained in these novel WC-SS composites. The existence of ductile films along grain boundaries and phase interface are responsible for the good mechanical properties, namely the excellent compromise between hardness and toughness attained in these WC-SS composites [1].
