(Received 16 August 2012; published 18 January 2013)

We investigate the atomic-scale tunneling characteristics of bilayer graphene on silicon carbide using the scanning tunneling microscopy. The high-resolution tunneling spectroscopy reveals an unexpected negative differential resistance (NDR) at the Dirac energy, which spatially varies within the single unit cell of bilayer graphene. The origin of NDR is explained by two near-gap van Hove singularities emerging in the electronic spectrum of bilayer graphene under a transverse electric field, which are strongly localized on two sublattices in different layers. Furthermore, defects near the tunneling contact are found to strongly impact on NDR through the electron interference. Our result provides an atomic-level understanding of quantum tunneling in bilayer graphene, and constitutes a useful step towards graphene-based tunneling devices.

Understanding quantum tunneling at the atomic level is essential in the study of nanoscale materials and their applications in the tunneling devices [1,2]. One of the most interesting tunneling phenomena is negative differential resistance (NDR), characterized by the reversal of the standard current-voltage relationship, decreasing current with increasing voltage. NDR is the basic operating principle of Esaki and resonant-tunneling diodes, and has enabled various novel applications [3,4]. Motivated by its fundamental importance and potential applications, there have been efforts to study NDR in graphene [5–9], a prototypical two-dimensional material with tunable electronic properties [10–13]. However, tunneling-induced NDR has not yet been realized in graphene, while a recent study has proposed a new method for NDR in graphene that is not based on the quantum tunneling effect [9].

The scanning tunneling microscope (STM) is a powerful tool, which can not only directly probe NDR, but also provide key information on the mechanism. STM has been widely employed to study various electronic properties of graphene at the atomic scale, such as scattering and interference [14,15], but investigation into the subunit cell regime has been limited. Here, we report the first observation of NDR based on quantum tunneling at the vertical junction of STM over bilayer graphene. The applied electric field across bilayer graphene induces two van Hove singularities in the electronic spectrum, which are strongly localized on two sublattices in different layers. Such a localization of electronic singularities leads to a novel atomic-scale variation of NDR, which is directly visualized by our high-resolution tunneling spectroscopy within the single unit cell of bilayer graphene. This result provides the atomic-level understanding of quantum tunneling in bilayer graphene.

Bilayer graphene was prepared on 6H-SiC(0001) wafers (N-dopant concentration of $1 \times 10^{18}$ cm$^{-3}$) by thermal graphitization in a flow of argon as described in Ref. [16]. The samples were transferred through the air to the ultrahigh vacuum chamber ($5 \times 10^{-11}$ torr), and briefly annealed up to 800 °C to refresh the surface. STM measurements were performed at 5.6 and 78.2 K using a commercial cryogenic STM (Unisoku, Japan), equipped with a Nanonis controller (Specs, Germany). $dI/dV$ spectra were obtained by the standard lock-in technique with a modulation voltage of $3–18$ mV at 500 Hz and a consistent set point of $−0.2$ V and 300 pA. The $dI/dV$ map was taken by a grid spectroscopy, for which the thermal drift was carefully compensated by the atom-tracking method.

The basic configuration of our experimental setup is shown in Fig. 1(a). It involves the tunnel junction of an STM tip and bilayer graphene separated by a vacuum gap of about 1 nm. Using this technique we can measure $I$-$V$ curves over a specific atomic site in the surface. The bilayer graphene is $n$ doped with Fermi energy ($E_F$) about 0.3 eV above the charge-neutrality point (the Dirac energy ($E_D$)). The interface of bilayer graphene with SiC(0001) produces a built-in electric field, rendering the charge densities in two stacked graphene layers inequivalent [17]. This out-of-plane symmetry breaking results in a band gap with the magnitude of 0.14 eV at $E_D$ [11]. This characteristic of bilayer graphene has enabled a tunable band gap either by gating [12] or chemical doping [11], and is also important for NDR as explained below.
Figure 1 (color online). (a) Experimental configuration for the local tunneling spectroscopy, consisting of an STM tip and bilayer graphene on silicon carbide. (b) STM topographic image (1.5 × 1.5 nm²) taken on bilayer graphene with sample bias of −0.2 V and tunneling current of 300 pA. Inset shows the atomic structure overlaid with part of the STM image. Balls are carbon atoms, and solid (dashed) lines represent chemical bonds in the top (bottom) layer. (c) Point—dI/dV spectrum and a corresponding I-V spectrum (inset) taken on the BT site. The red line overlaid is the result of model simulations. Red arrows highlight NDR. (d) dI/dV spectra normalized by I-V at each initial setting current marked. Dotted lines in (c) and (d) indicate conductance zero.

Figure 1(b) shows an STM topographic image of bilayer graphene, acquired with −0.2 V sample bias and constant tunneling current. The atomic structure of bilayer graphene is shown in the inset and overlaid with part of the image for comparison. Bilayer graphene consists of two Bernal stacked graphene layers, where the A sublattice of the top layer (AT, black) is located on the B sublattice of the bottom layer (BT). Due to the direct coupling between them, the other sublattice in the top layer (BT, red) is dominantly imaged at low-bias voltage, resulting in the triangular pattern [18,19]. The full honeycomb lattice could be visualized at the higher bias voltage, confirming the characteristic bias dependence of bilayer graphene [20,21]. In Fig. 1(b), one can also readily distinguish the AT site from the hollow site in the top layer (corresponding to BT, blue) by their relative brightness. This demonstrates the high spatial resolution achieved in our measurements.

Figure 1(c) shows a dI/dV curve measured on the BT site. The differential conductance value goes below zero at −0.3 V, indicative of negative conductance (or resistance). This can also be directly seen in I-V measurements [inset of Fig. 1(c)] as decreasing current while increasing the voltage from −0.26 to −0.34 V. This observation clearly demonstrates NDR in bilayer graphene. The NDR behavior was reproducibly observed in the voltage range of −0.30 to −0.35 V, close to ED. In Fig. 1(d), we display a series of dI/dV spectra normalized by 1/V taken with different initial tunneling currents, which are inversely related to the tip-sample distance (tunneling barrier width). They show little change and consistent NDR behaviors, excluding tip-induced origins of NDR such as a local band bending [22].

An important clue for the origin of NDR can be obtained from its spatial distribution at the atomic scale. Figure 2(a) compares dI/dV curves on three different atomic sites [refer to Fig. 1(b)]. NDR at −0.3 V occurs only on the BT site, while above +0.1 V the dominant conductance is found on the AT site. Recording dI/dV curves as a function of lateral tip positions, we show a differential conductance map at −0.3 V in Fig. 2(b). The simultaneously acquired topographic image in the inset helps determine the atomic position. Interestingly, negative conductance, represented by blue color, is centered on each BT atom and is surrounded by a hexagonal rim of positive conductance. This suggests that NDR is closely linked to localized states at the BT site. On the other hand, the same map taken at +0.17 V shows dominant positive conductance on the AT site. This site-resolved detail has not been observed previously most likely due to limited spatial resolution in the tunneling spectroscopy. Indeed, the spatial average of dI/dV curves [the black one in Fig. 2(a)] reproduces the typical curve with no NDR reported previously in literature [19].

To understand the origin of NDR, let us recall the band structure of bilayer graphene near EF as illustrated...
in Fig. 3(a). In pristine bilayer graphene, there are two pairs of energy bands (dotted lines)—a low-energy pair from the $B_T$ and $A_B$ atoms and a high-energy pair from the $A_T$ and $B_B$ atoms. When a band gap is induced by a transverse electric field, the low-energy bands develop a Mexican-hat-like dispersion at conduction and valence band edges near the band gap [23,24]. This rather flat dispersion leads to two distinct van Hove singularities in the density of states [25] as in Fig. 3(b). Furthermore, these two near-gap states were theoretically predicted to be localized at specific atomic sites in different layers, as shown in Figs. 3(a) and 3(b), depending on the direction of the electric field [26,27]. Such a strong localization of electronic singularities (the flat parts of energy bands) is also important in understanding many-body correlations at low energies and the ground state of bilayer graphene [28], but has not been directly shown by experiments.

In our case, states near $-0.25$ and $-0.39$ eV are localized at $B_T$ in the top layer (red) and at $A_B$ in the bottom layer (blue), respectively, while states near $+0.1$ eV are localized at $A_T$ in the top layer (black). Since STM is highly sensitive to the local density of states in the surface, this explains dominant conductance at $B_T$ for $-0.2 \sim +0.1$ V in Fig. 2(a) and that at $A_T$ above $+0.1$ V in Figs. 2(a) and 2(c). This picture is fully supported by the energy-distribution curve at the $K$ point [Fig. 3(c)], measured by angle-resolved photoemission spectroscopy (ARPES). It reveals highly asymmetric intensities for the two van Hove singularities [11], because the photoelectrons excited from the bottom layer ($A_B$) are attenuated by scattering during their passage though the top layer. This also confirms that the layer localization is universal over the wide area covered by the photon beam ($\sim 50$ $\mu$m in radius) in ARPES.

The presence of a layer-polarized van Hove singularity can qualitatively explain NDR, as in Fig. 3(d), which shows the relationship between the broadened sample density of states at $B_T$ and the tip density of states. When the sample bias equals $V_0$, where the van Hove singularity meets the $E_F$ of the tip, the current reaches a local maximum, $I_{\text{max}}$. As it approaches $V_1$, where the van Hove singularity no longer assists tunneling and no state exists in the band gap, tunneling is strongly suppressed, and the current decreases down to $I_{\text{min}}$. As the voltage further increases out of the band gap, the current starts increasing again, resulting in the $N$ shaped branch in the $I-V$ curve [as in the inset of Fig. 1(c)]. That is, the observed NDR is the result of electronic spectrum reconstructions in asymmetric bilayer graphene.

For the quantitative analysis, we performed $I-V$ simulations based on the standard formula, $I(V, z) \sim \int_{E_F}^{E_F} \sqrt[2]{\text{DOS}_\text{sample}(E + V) \text{DOS}_\text{tip}(E) T(E, V, z)} dE$, where DOS is the density of states and $T$ is the tunneling matrix element $[29–31]$. $T$ is estimated by the WKB approximation as $T(E, V, z) = \exp(-2\sqrt{2} \phi / V/2 - E)z$, where $\phi$ is the work function. We used the Gaussian-broadened local DOS in the theoretical calculation [26,27] at $B_T$ with a small contribution of that at $A_T$ (to take into account the finite areal averaging). The tip DOS is assumed to have a typical localized state of tip-apex atoms near $E_F$ [29]. The sample and tip DOS’s optimized to reproduce the experimental data are presented, respectively, by red and gray curves in Fig. 3(d). The simulated curve [the red line overlaid in Fig. 1(c)] successfully reproduces the NDR behavior, confirming the proposed mechanism.

To further support the proposed mechanism, we have investigated the interaction of NDR with local defects. Recent theories predict that a single point scatterer in bilayer graphene develops in-gap states, suppressing the sharp van Hove singularities [32,33]. Thus, one might expect a local suppression of NDR near defects. Figure 4(a) shows a large scale STM image of an impurity (yellow blob).
The $dI/dV$ maps taken at two different locations about 16 nm away from defects are present in Figs. 4(b) and 4(c). NDR is extinguished in a subset of $B_T$ atoms, which form a periodic $\sqrt{3} \times \sqrt{3}$ pattern rotated by $30^\circ$ with respect to the lattice constant, and these data show little dependence on the origin and site of defects. The $(\sqrt{3} \times \sqrt{3})R30^\circ$ modulation is the well-known signature of intervalley electron scattering by a defect in bilayer graphene [14,15]. Thus, we attribute two inverse patterns in Figs. 4(b) and 4(c) to constructive or destructive interference of defect scatterings, as illustrated in Figs. 4(e) and 4(f). Furthermore, the same map taken right next to a defect [Fig. 4(d)] shows that NDR completely disappears and instead strong positive conductance emerges on a subset of $B_T$ atoms. As a result, positive, zero, and negative conductance are all possible [solid line in Fig. 4(g)], and defects can be used to switch NDR on and off nearby as well as at the site more than 10 nm away from a defect. Such a strong impact of defects in electronic localization should be considered for the complete understanding of scattering and interference in bilayer graphene [14,15]. The disappearance of NDR with the progressive suppression of the van Hove singularity near the band gap [the peak at $-0.23$ V in Fig. 4(g)] makes a clear link between them. This will further allow the control of NDR by tuning the band gap with gating or chemical doping [11,12].

Our results, combined with a few existing techniques, suggest a route towards graphene-based NDR devices. The key to NDR is, as demonstrated here, to exploit the near-gap van Hove singularity in biased bilayer graphene. In our experimental configuration, the tip can be replaced by another biased bilayer graphene, such that a vertical tunnel junction of two graphene bilayers is formed. A similar graphene heterostructure has recently been realized using ultrathin boron nitride films as a tunneling barrier [1,2]. In such junctions, tunneling would depend on sublattice-registry matching. That is, if the sublattices in two graphene layers facing each other, where the van Hove singularity is localized, were to line up, maximal direct tunneling between van Hove singularities could be achieved. The tunable electronic structure of bilayer graphene [11,34,35] would thus allow further optimization for NDR and a large peak-to-valley ratio of tunneling current.
