(Received 16 June 2011; published 30 September 2011)

The general relativistic (Mercury-type) periastron advance is calculated here for the first time with exquisite precision in full general relativity. We use accurate numerical relativity simulations of spinless black-hole binaries with mass ratios 1/8 ≤ m1/m2 ≤ 1 and compare with the predictions of several analytic approximation schemes. We find the effective-one-body model to be remarkably accurate and, surprisingly, so also the predictions of self-force theory [replacing m1/m2 → m1 m2/(m1 + m2)2]. Our results can inform a universal analytic model of the two-body dynamics, crucial for ongoing and future gravitational-wave searches.

Introduction.—The anomalous rate of Mercury’s perihelion advance was originally recognized in 1859 by the astronomer Urbain Le Verrier. For the first time, Newton’s law of universal gravitation could not be reconciled with observation. Treating Mercury as a test body in free fall in the gravitational field generated by the mass M⊙ of the Sun, Einstein derived the lowest order (weak-field) general relativistic angular per cent per century,

where a and e are the semimajor axis and eccentricity of Mercury’s orbit, respectively. Equation (1) perfectly accounted for the observed discrepancy of ~43′′ per century, thus providing the first successful test of general relativity. More recently, the same effect—but with a much larger amplitude, of the order a few degrees per year—has been observed in the orbital motion of binary pulsars [2]. Today, the exciting prospects of observing gravitational waves from the inspiral and merger of compact binaries, by using interferometric detectors like LIGO or Virgo, provide a modern context for the problem of relativistic periastron advance and a motivation to go far beyond Einstein’s weak-field test-particle approximation.

In this Letter, we restrict our attention to binaries composed of two black holes. Their orbital dynamics can be analyzed by using several approximation schemes in general relativity: post-Newtonian expansions [3], black-hole perturbation theory [4], and the effective-one-body model [5]. It can also be studied by using fully nonlinear numerical relativity (NR). While NR can now routinely perform accurate binary black-hole simulations [6], approximation methods remain valuable given the high computational cost of these simulations and their restricted utility when the mass ratio is too extreme. It is important to assess the predictions of the various approximations against the NR benchmark, since (i) it allows crucial cross-validation tests, (ii) it helps delineate the respective domains of validity of each method, and (iii) it can inform the development of a universal semianalytical model of the binary dynamics.

Neglecting radiation reaction, the motion of two non-spinning black holes on a generic eccentric orbit involves two frequencies: the radial frequency (or mean motion) Ωr and the averaged angular frequency Ωφ defined by

where P is the radial period, i.e., the time interval between two successive periastron passages, ϕ = dϕ/dt is the time derivative of the orbital phase ϕ(t), and ΔΦ/(2π) = K − 1 is the fractional advance of the periastron per radial period. In the circular orbit limit, the relation between K = Ωφ/Ωr and Ωφ is coordinate invariant (for a large class of physically reasonable coordinate systems) and therefore provides a natural reference for comparing between the predictions of the analytical and numerical methods currently available.

In this Letter, we present new accurate NR simulations starting at lower orbital frequencies than in previous work [7–9]. We outline the respective computations of the invariant relation K(Ωφ) in numerical relativity, post-Newtonian theory, the effective-one-body formalism, and black-hole perturbation theory. We then perform an extensive comparison which, for the first time, (i) encompasses all of these methods and (ii) focuses on the orbital dynamics of the binary, rather than the asymptotic gravitational waveform. We also discuss the implications for the
Numerical relativity.—The periastron advance of non-spinning black-hole binaries was estimated for the first time in general relativistic numerical simulations in Ref. [10]. In the present work, we improve considerably on the accuracy of these calculations. Our results are based on new and longer simulations of the late stage of the inspiral of black-hole binaries, using the Spectral Einstein Code spEC [11,12], with mass ratios \(q = m_1/m_2\) between 1:1 and 1:8 and eccentricities \(e\) in the range \([0.0015, 0.023]\). These runs are summarized in Table I and will be described in detail elsewhere [9,13]. (Reference [10] discusses the definition of \(e\) in these simulations.)

We compute \(\Omega_\varpi\) and \(\Omega_r\), by using the orbital frequency \(\Omega(t)\) extracted from the motion of the apparent-horizon centers (in harmonic coordinates): Let \(c_i(t)\) be the coordinates of the center of each black hole, and define their relative separation \(r = c_1 - c_2\); then \(\Omega = |r \times \dot{r}|/r^2\), where the Euclidean cross product and norm are used. The frequency \(\Omega(t)\) can be written as the sum of a secular piece (given by the average frequency \(\Omega_\varpi\)) and a small oscillatory remainder—both of which drift slowly in time due to radiation reaction. To compute \(K_{\text{NR}}\) at some coordinate time \(T\), we choose a time interval of width \(W = 2 \pi/\Omega(T)\), centered on \(T\), and fit \(\Omega(t)\) to the model \(\Omega(t) = p_0 (p_1 - t)^{p_2} + p_3 \cos[p_4 + p_6 (t - T) + p_5 (t - T)^2]\), where the \(p_j\)'s are fitting parameters. We then write \(\Omega_\varpi(T) = p_0 (p_1 - T)^{p_2}\) and \(\Omega_r(T) = p_3\), compute the ratio \(K_{\text{NR}}(T) = \Omega_\varpi(T)/\Omega_r(T)\), and hence obtain \(K_{\text{NR}}\) as a function of \(\Omega_\varpi\). Finally, we fit \(K_{\text{NR}}(\Omega_\varpi)\) to a smooth quadratic polynomial by using

\[K_{\text{NR}} = [a_0 + a_1 (m_\varpi) + a_2 (m_\varpi)^2]K_{\text{Schw}},\tag{3}\]

where \(m = m_1 + m_2\) is the total mass of the binary. The results of the fits are given in Table I. For convenience, the numerical periastron advance \(K_{\text{NR}}\) is normalized by the test-particle result \(K_{\text{Schw}}\), which is known in closed form as \([14,15]\)

\[K_{\text{Schw}} = (1 - 6e^2)^{-1/2}, \quad \text{where } x = (m_\varpi)^{2/3}\]

is the usual dimensionless coordinate invariant post-Newtonian parameter.

The variance in the numerical data for various window sizes \(W\) provides an estimate of the error in \(K_{\text{NR}}\). We point out that the finite (nonzero) eccentricity in the NR simulations introduces a small error, since we are interested in the \(e \rightarrow 0\) limit. However, as the leading-order result (1) suggests, and calculations at higher post-Newtonian (PN) orders confirm, this error scales like \(e^2\), which in our simulations is always \(\lesssim 5 \times 10^{-4}\) and decreasing monotonically with time.

The numerical data form the basis for our comparisons. We will now discuss the different approximation schemes in turn, summarizing the results in Figs. 1 and 2 (showing \(K\) as a function of frequency for two fixed mass ratios) and Fig. 3 (showing \(K\) as a function of mass ratio for a given frequency).

Post-Newtonian theory.—Einstein’s result (1) was generalized to arbitrary masses \(m_1\) and \(m_2\) by Robertson [16]. Following the discovery of binary pulsars in the 1970s, an improved modeling of the orbital dynamics of these compact binaries was required, leading to the extension of this 1PN result to 2PN order [14]. As usual, we refer to \(n\)PN as the order equivalent to terms \(O(c^{-2n})\) in the equations of motion beyond the Newtonian acceleration. More recently, the need for extremely accurate gravitational-wave templates modeling the inspiralling phase of coalescing compact binaries motivated the computation of the equations of motion through 3PN order. These results allowed also the calculation of the periastron advance at the 3PN accuracy for eccentric orbits [17].

### Table I. Simulation parameters. Here \(q = m_1/m_2\), \(m = m_1 + m_2\), \(d\) is the initial coordinate separation, \(e\) is the initial eccentricity, and \(N_{\text{orb}}\) is the total number of orbits in the simulation. The fitting parameters \([a_0, a_1, a_2]\) [cf. Eq. (3)] are computed for the restricted frequency range \(\Omega_i \leq \Omega_\varpi \leq \Omega_f\).

FIG. 1 (color online). The periastron advance \(K\) of an equal mass black-hole binary, in the limit of zero eccentricity, as a function of the orbital frequency \(\Omega_\varpi\) of the circular motion. The NR results are indicated by the cyan-shaded region. The PN and EOB results are valid at 3PN order. The lower panel shows the relative difference \(\delta K/K = (K - K_{\text{NR}})/K_{\text{NR}}\).
This suggests that the exact 

\[ K_{3PN} = 1 + 3x + \left( \frac{27}{2} - 7\nu \right)x^2 \]

\[ + \left( \frac{135}{2} - \frac{649}{32}\pi^2 \right) + 7\nu^2 \] 

\[ + O(x^3). \] (4)

The symmetric mass ratio \( \nu = m_1m_2/m^2 \) is such that \( \nu = 1/4 \) for an equal mass binary and \( \nu \rightarrow 0 \) in the extreme mass-ratio limit. The term \( \propto \nu^2 \) in Eq. (4), which is a 3PN effect, contributes less than 1% to \( K_{3PN} \) for all mass ratios. This suggests that the exact \( K \) may be well approximated by a linear function of \( \nu \). Figures 1–3 show a good agreement between the 3PN and NR results for \( q = 1 \), with \( \approx 1\% \) relative difference even at the high-frequency end. However, the performance of the PN approximation deteriorates with decreasing \( q \).

**Effective-one-body (EOB) method.**—The EOB formalism [5] maps the conservative part of the PN dynamics of a compact binary system onto the dynamics of a test particle of reduced mass \( m = m_1m_2/m \) in a time-independent and spherically symmetric effective metric

\[ ds^2_{eff} = -A(r; \nu)dt^2 + B(r; \nu)d\nu^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2), \]

which reduces to the Schwarzschild metric of a black hole of mass \( m \) in the limit \( \nu \rightarrow 0 \). The expansions of the EOB potentials \( A \) and \( \bar{D} \equiv (AB)^{-1} \) in terms of the Schwarzschild-like coordinate \( u = m/r \) are known through 3PN order as [5,18] \( A = 1 - 2u + 2\nu u^3 + \left( \frac{19}{3} - \frac{1}{3}\pi^2 \right)\nu u^4 + O(u^5) \) and \( \bar{D} = 1 + 6\nu u^2 + (52 - 6\nu)u^4 + O(u^6) \), respectively. To enforce the presence of an EOB innermost stable circular orbit (ISCO), Ref. [18] suggested replacing \( B \) by its Padé approximant of order \( 1,3 \), \( A_{np} = (1 + au)/(1 + bu + cu^2 + du^4) \), whose Taylor series coincides with the known 3PN result.

From the recent analysis of slightly eccentric orbits in the EOB formalism [19], the effective-one-body prediction for the periastron advance in the limit of zero eccentricity is given by

\[ K_{EOB} = \sqrt{\frac{A_p'(u)}{D(u)\Delta(u)}}. \] (5)

where \( A_p' = dA_p/du \) and \( \Delta = A_pA_p' + 2uA_pA_p'' - uA_pA_p'' \) vanishes at the EOB ISCO. To obtain the invariant relation \( K_{EOB}(x) \), one needs to compute \( u \) given \( x \), which we do here numerically (for any given \( \nu \)) from the expression of the EOB Hamiltonian restricted to circular orbits, and Hamilton’s equations of motion [19]. The resulting curves are displayed in red in Figs. 1–3. For \( q = 1 \) and \( 2/3 \), the EOB(3PN) prediction (5) is within the numerical error up to \( m\Omega_\varphi \sim 0.022 \). For all the other mass ratios, the EOB (3PN) result is within the numerical error at all frequencies. When using the EOB potential \( A(u) \) with 4PN and 5PN terms calibrated to a set of highly accurate unequal mass nonspinning binary black-hole simulations [20], the EOB prediction is within the numerical error at all frequencies and for all mass ratios considered. This remarkable agreement could be attributed in part to the “polelike” structure at the EOB ISCO in Eq. (5), which is absent from the standard PN result (4).

**Perturbation theory and the gravitational self-force.**—Extreme mass-ratio inspirals of compact objects into massive black holes, for which \( m_2 \gg m_1 \), are important sources of low-frequency gravitational radiation for future space-based detectors. Modeling the dynamics of these systems requires going beyond the geodesic approximation, by taking into account the backreaction effect due to

FIG. 2 (color online). The same as in Fig. 1, but for a mass ratio \( q = 1/8 \). Note that for an orbital frequency \( m\Omega_\varphi \sim 0.03 \), corresponding to a separation \( r \sim 10m \), the periastron advance reaches half an orbit per radial period.

For quasicircular orbits, combining Eqs. (5.8) and (5.25) of Ref. [17], we obtain the 3PN-accurate expression of \( K \) as

\[ K_{3PN} = 1 + 3x + \left( \frac{27}{2} - 7\nu \right)x^2 \]

\[ + \left( \frac{135}{2} - \frac{649}{32}\pi^2 \right) + 7\nu^2 \] 

\[ + O(x^3). \] (4)

The symmetric mass ratio \( \nu = m_1m_2/m^2 \) is such that \( \nu = 1/4 \) for an equal mass binary and \( \nu \rightarrow 0 \) in the extreme mass-ratio limit. The term \( \propto \nu^2 \) in Eq. (4), which is a 3PN effect, contributes less than 1% to \( K_{3PN} \) for all mass ratios. This suggests that the exact \( K \) may be well approximated by a linear function of \( \nu \). Figures 1–3 show a good agreement between the 3PN and NR results for \( q = 1 \), with \( \approx 1\% \) relative difference even at the high-frequency end. However, the performance of the PN approximation deteriorates with decreasing \( q \).

**Effective-one-body (EOB) method.**—The EOB formalism [5] maps the conservative part of the PN dynamics of a compact binary system onto the dynamics of a test particle of reduced mass \( m = m_1m_2/m \) in a time-independent and spherically symmetric effective metric

\[ ds^2_{eff} = -A(r; \nu)dt^2 + B(r; \nu)d\nu^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2), \]

which reduces to the Schwarzschild metric of a black hole of mass \( m \) in the limit \( \nu \rightarrow 0 \). The expansions of the EOB potentials \( A \) and \( \bar{D} \equiv (AB)^{-1} \) in terms of the Schwarzschild-like coordinate \( u = m/r \) are known through 3PN order as [5,18] \( A = 1 - 2u + 2\nu u^3 + \left( \frac{19}{3} - \frac{1}{3}\pi^2 \right)\nu u^4 + O(u^5) \) and \( \bar{D} = 1 + 6\nu u^2 + (52 - 6\nu)u^4 + O(u^6) \), respectively. To enforce the presence of an EOB innermost stable circular orbit (ISCO), Ref. [18] suggested replacing \( B \) by its Padé approximant of order \( 1,3 \), \( A_{np} = (1 + au)/(1 + bu + cu^2 + du^4) \), whose Taylor series coincides with the known 3PN result.

From the recent analysis of slightly eccentric orbits in the EOB formalism [19], the effective-one-body prediction for the periastron advance in the limit of zero eccentricity is given by

\[ K_{EOB} = \sqrt{\frac{A_p'(u)}{D(u)\Delta(u)}}. \] (5)

where \( A_p' = dA_p/du \) and \( \Delta = A_pA_p' + 2uA_pA_p'' - uA_pA_p'' \) vanishes at the EOB ISCO. To obtain the invariant relation \( K_{EOB}(x) \), one needs to compute \( u \) given \( x \), which we do here numerically (for any given \( \nu \)) from the expression of the EOB Hamiltonian restricted to circular orbits, and Hamilton’s equations of motion [19]. The resulting curves are displayed in red in Figs. 1–3. For \( q = 1 \) and \( 2/3 \), the EOB(3PN) prediction (5) is within the numerical error up to \( m\Omega_\varphi \sim 0.022 \). For all the other mass ratios, the EOB (3PN) result is within the numerical error at all frequencies. When using the EOB potential \( A(u) \) with 4PN and 5PN terms calibrated to a set of highly accurate unequal mass nonspinning binary black-hole simulations [20], the EOB prediction is within the numerical error at all frequencies and for all mass ratios considered. This remarkable agreement could be attributed in part to the “polelike” structure at the EOB ISCO in Eq. (5), which is absent from the standard PN result (4).

**Perturbation theory and the gravitational self-force.**—Extreme mass-ratio inspirals of compact objects into massive black holes, for which \( m_2 \gg m_1 \), are important sources of low-frequency gravitational radiation for future space-based detectors. Modeling the dynamics of these systems requires going beyond the geodesic approximation, by taking into account the backreaction effect due to
the interaction of the small object with its own gravitational perturbation. This “gravitational self-force” (GSF) effect has recently been computed for generic (bound) geodesic orbits around a Schwarzschild black hole [21–23]. In particular, the O(q) correction to the test-mass result \( K_{\text{Schw}} \) has been derived [24]. This calculation determined (numerically) the term \( \rho(x) \) in the function \( W = 1/K^2 = 1 - 6x + q\rho(x) + O(q^2) \). The results are well fitted (at the 10\(^{-5}\) level) by the rational function \( \rho = 14x^2(1 + \alpha x)/(1 + \beta x + \gamma x^2) \), with \( \alpha = 12.9906, \beta = 4.57724, \gamma = -10.3124 \). (This model improves upon the model of Ref. [24]; it is based on a much denser sample of GSF data points in the relevant frequency range.)

In terms of the quantity \( K \) we have

\[
K_{\text{GSF}}^q = \frac{1}{\sqrt{1 - 6x}} \left[ 1 - \frac{q}{2} \frac{\rho(x)}{1 - 6x} + O(q^2) \right].
\]

We used this expression, with the above analytic fit for \( \rho(x) \), to produce the dashed blue curves in Figs. 1–3.

Since \( \rho(x) > 0 \) for all stable circular orbits, the O(q) GSF decreases the rate of precession. Note that the formal divergence of \( K_{\text{GSF}}^q \) at the ISCO limit (\( x \rightarrow 1/6 \)) is simply a consequence of the fact that \( \Omega_x \) vanishes there (by definition), while \( \Omega_x \) remains finite. This divergence might explain why the convergence of the standard PN series seems to deteriorate with decreasing \( q \) [25], as also illustrated by our results (cf. Fig. 3). We remind the reader that Eq. (6) captures only the conservative effect of the GSF and has a limited physical relevance near the ISCO, where the actual dynamics transitions from an adiabatic quasicircular inspiral (driven by the dissipative piece of the GSF) to a direct plunge [26,27].

We now turn to discuss one of the most striking findings of our study. Since \( q = \rho(q)/(1 + q)^2 \) coincide at leading order, namely, \( q = \nu + O(\nu^2) \), we may recast Eq. (6) as

\[
K_{\nu}^q = \frac{1}{\sqrt{1 - 6x}} \left[ 1 - \frac{\nu}{2} \frac{\rho(x)}{1 - 6x} + O(\nu^2) \right],
\]

which, unlike \( K_{\text{GSF}}^q \), is symmetric under \( m_1 \leftrightarrow m_2 \). The solid blue curves in Figs. 1–3 show \( K_{\nu}^q \). Remarkably, while the agreement between \( K_{\text{GSF}}^q \) and \( K_{\nu}^q \) becomes manifest only at sufficiently small \( q \) (as expected), \( K_{\nu}^q \) appears to agree extremely well with \( K_{\nu}^q \) at all mass ratios. This suggests that the substitution \( q \rightarrow \nu \) amounts to an efficient “resummation” of the \( q \) expansion, to the effect that much of the functional form \( K(x) \) is captured by the \( O(\nu) \) term, even for large \( q \).

A few heuristic explanations for this behavior may be suggested. (i) As mentioned earlier, quadratic corrections in \( \nu \) enter the PN expression for \( K \) only at 3PN [recall Eq. (4)] and account for less than 1% of \( K \) at this order. This implies that the linear-in-\( \nu \) approximation must be very accurate, at least at small frequencies. (ii) The true function \( K(x; m_1, m_2) \) must be invariant under exchange \( m_1 \leftrightarrow m_2 \). The expansion in \( \nu \), \( K_{\nu}^q \), satisfies this symmetry by definition of \( \nu \), whereas the expansion in \( q \), \( K_{\text{GSF}}^q \), does not. (iii) Assuming the coefficients \( a_n \) in the formal expansion \( K = \sum a_n(x)\nu^n \) do not increase with \( n \) (which, however, only a future calculation of higher-order GSF terms could confirm), this expansion will exhibit a fast convergence since \( 0 < \nu \lesssim 1/4 \); the same cannot be said of the \( q \) expansion.

Comparison of the GSF curves in Figs. 1–3 with the NR benchmark leads us to yet another important observation. It is evident that the second-order GSF correction to \( K \) (i.e., the unknown term \( \propto q^2 \)) has an opposite sign with respect to the first-order term; namely, the second-order GSF acts to increase the rate of periastron advance. This is a new result, which illustrates the potential merit of cross-cultural comparisons of the kind advocated in this work.

**Summary and discussion.**—The advent of precision-NR technology allows us, for the first time, to extract accurate information about the local dynamics in binary black-hole inspirals (previous studies focused primarily on asymptotic waveforms) and carry out meaningful comparisons with the results of analytic approaches to the problem. These comparisons and cross-check validations among analytic approximants and NR results are crucial for developing faithful analytic waveforms to be used in LIGO or Virgo searches.

Here we focused on a particular aspect of the dynamics, namely, the relativistic periastron advance. We worked in a highly relativistic regime, where the periastron advance can reach values as high as half an orbit per radial period (far greater than the meagre \( \sim 43^\circ \) per century advance of Mercury’s perihelion). We employed the invariant relation \( \Omega_\nu \) as a reference for comparison, which is meaningful only in the adiabatic regime where the dissipative evolution is “slow.” For the range of inspiral orbits covered by our NR simulations, a measure of adiabaticity is provided by \( 0.3\% \lesssim \Omega_\nu/\Omega_{\text{ISCO}} \lesssim 1.7\% \). This suggests that inclusion of dissipative effects in the PN, EOB, or GSF results would not substantially affect our conclusions. The very good agreement between the analytical and NR results at low frequency, where the error in \( K_{\nu}^q \) is smallest, also supports this expectation.

Our direct comparison between perturbative and full NR results is the first of its kind. The O(q) GSF prediction agrees with the NR data for small mass ratios (e.g., \( q = 1/8 \) or 1/6) to within a relative difference of magnitude \( \sim q^2 \), as expected. This provides an extremely strong validity test for both NR and GSF calculations. Furthermore, the sign and magnitude of the difference \( K_{\nu}^q - K_{\text{GSF}}^q \) give us valuable, hitherto inaccessible information about the second-order GSF effect.

The above validation test is further reinforced by the 3PN result, which shows a good agreement with the NR data at small frequencies, or “large” separations (down
to $r \sim 10m$), especially for comparable masses (e.g., for $q = 1$ or $2/3$). Our comparison also reaffirms the expectation that the PN approximation performs less well in the small mass-ratio regime.

We find that the EOB(3PN) prediction of the periastron advance is in very good agreement with the numerical one across the entire range of mass ratios and frequencies considered. This result supports the idea that the EOB formalism can describe the binary dynamics at all mass ratios.

Finally, we observe that the simple replacement $q \rightarrow \nu$ can extend the validity of the GSF approximation far beyond the extreme mass-ratio inspiral regime. Indeed, our model $K_{\text{GSF}}$ agrees very well with the NR data at all frequencies and for all mass ratios considered, including the equal mass case. This surprising result suggests that GSF calculations may very well find application in a broader range of physical problems than originally envisaged, including the modeling of intermediate mass-ratio inspirals, a plausible source of gravitational waves for Advanced LIGO or Virgo [28].
