ABSTRACT

Aims. We use 5 years of Fermi-LAT data towards the Galactic-centre giant molecular cloud complex, Sagittarius B, to test questions of how well-mixed the Galactic component of cosmic rays are and what the level of the cosmic-ray sea in different parts of the Galaxy is.

Methods. We use dust-opacity maps from the Planck satellite to obtain independent methods for background subtraction and an estimate for the mass of the region. We then present high-quality spectra of γ-ray emission from 0.3 to 30 GeV and obtain an estimate of the cosmic-ray spectrum from the region.

Results. We obtain an estimate of the mass of the region of 1.5 ± 0.2 × 10^5 M⊙ using the Planck data, which agrees well with molecular-line-derived estimates for the same region. We find the the γ-ray flux from this region is fitted well with a cosmic-ray spectrum that is the same as is observed locally, with evidence of a small over-density at intermediate (1–10 GeV) energies.

Conclusions. We conclude that the γ-ray and cosmic-ray spectrum in the region can be well-fitted using a local cosmic-ray spectrum.

1. Introduction

Cosmic ray (CR) acceleration and propagation theory suggests that up to energies of ~ 10^15 eV, Galactic CRs should be well mixed throughout the Galaxy. It is these CRs that constitute the well-known CR sea, which should describe the average density of CRs throughout the Galactic disk (Strong et al. 2007) and can be treated as the level of the sea of Galactic CRs. However, significant questions of just how well-mixed and isotropic the CR sea is remain unanswered. In particular, it is not clear just how strong the effect of, for example, (unknown) local CR sources (Montmerle 1979; Yang et al. 2014) or how CR mixing on intermediate (up to a few kpc) scales affects both the normalisation and spectral behaviour of the CR sea. As discussed below, nearby (< 1 kpc) molecular clouds make good targets for testing the level of the CR sea (Yang et al. 2014 and references therein); however, variations either on intermediate size scales (e.g. a few kpc) or elsewhere in the Galaxy cannot be ruled out.

One of the most attractive methods of probing the structure of the CR sea is through analysing passive CR targets, such as giant molecular clouds (GMCs; e.g. Aharonian 1991, 2001, Casanova et al. 2010, Pedaletti et al. 2013). However, this method requires accurate spectroscopic measurements to obtain reliable estimates to the distance d and mass, M⊙ (here M⊙ is the mass of the GMC in units of 10^4 M⊙) of the pertinent GMC, and the ratio of these parameters, M⊙/d, necessarily limits its accuracy. Additionally, the competition of different γ-ray radiation mechanisms, such as pion-decay, non-thermal bremsstrahlung, and inverse-Compton (IC) losses, should also be considered in any account of the accuracy of this method. Nevertheless, previous studies (Neronov et al. 2012, Ackermann et al. 2012, Yang et al. 2014) using this method have been performed on the nearby GMCs in the Gould Belt, and they confirm that the level of the CR sea within 1 kpc is nearly identical to the local measurement. However, the 1/d^2 relation of the γ-ray luminosity has limited our ability to obtain valuable information about the CR-sea in regions farther afield than these clouds.

To compensate for the decreased γ-ray luminosity, clouds of increased mass will also serve as ideal candidates to probe the level of the CR sea in other regions of the Galaxy. The Sagittarius B (Sgr B) complex, which is one of the most active and massive molecular cloud complexes in the Galaxy (viz. ~ 10^5 M⊙, Tsuboi et al. 1999), represents an ideal target for improving our knowledge of the CR sea. That this cloud is located about ~ 100 pc from the Galactic centre (GC) adds importance to obtaining γ-ray emission from this region. Indeed, although the distance to the GC is large, the ratio M⊙/d^2 is still about 10^3, although a little less than for the best candidates in the Gould Belt, and the smaller angular size of this source results in even higher signal-to-noise ratio.

On the other hand, because of the GC’s high gas and dust content (~ 10% of the total gas content of the Galaxy in ~ 1% of the volume over the inner ~ 400 pc; Crocker et al. 2011), the high areal supernova rate (SNR) (viz. ~ 0.4/century; Crocker et al. 2011), and the high total magnetic field strength of ~ 130 μG (Crocker et al. 2010), it is too complex and difficult a region for drawing definite conclusions. Additionally, it is believed to be a potential source of Galactic CRs (Ginzburg & Ptuskin 1976, Ptuskin & Khazanov 1981), so one should exercise a modicum of caution when analysing observational results from this region.

The determination of the CR density near GC would be important for understanding the particle acceleration and origins.
of Galactic CRs. This motivated us to analyse the Fermi-LAT data for the GC region. With the γ-ray data from 300 MeV to 30 GeV and a new parametrisation for γ-ray production due to neutral pion decay in proton-proton collision (Kafexhiu et al. 2014), we derive the CR spectrum. The derived CR spectrum is consistent in shape with the direct measurements of local CRs by the PAMELA (Adriani et al. 2011) at the top of the Earth’s atmosphere.

We have structured the paper as follows. In Section 2, we present the results of our analysis of the Fermi-LAT observations and discuss the observational uncertainties of our procedure. In Section 3 we discuss the γ-ray flux from the region, as well as our derivation of the mass from the dust opacity maps and derivation of the CR spectra and fluxes, assuming that γ-rays are produced in interactions of CR protons and nuclei (hereafter simply CRs) with the ambient gas and finally discuss the implications of the results. We present our conclusions in Section 4.

2. Results

2.1. Fermi-LAT data analysis

We selected observations for which the Fermi-LAT detector was pointed towards the Sgr B complex (MET 2395574177 - MET 4081563951), which contains data over a period of approximately five years. For this analysis, we used the standard LAT analysis software package v9r32p5.1.2

Given the crowded nature of the region and to avoid systematic errors due to poor angular resolution and uncertainties in the effective detection area at low energies, we selected only events with energy exceeding 300 MeV. The region of interest (ROI) was selected to be a $10^\circ \times 10^\circ$ square centred on the position of GC. To reduce the effect of the Earth albedo background, we excluded from the analysis the time intervals when the Earth was in the field of view (specifically when the centre of the field of view was more than $52^\circ$ from zenith), as well as the time intervals when parts of the ROI had been observed at zenith angles $> 100^\circ$. The spectral analysis was performed based on the P7rep_v15 version of post-launch instrument response functions (IRFs). Both the front and back converted photons were selected.

2.2. Background subtraction

Since the γ-rays produced in molecular clouds are already included in the galactic diffuse model provided by the Fermi collaboration, it cannot be used to evaluate the background. The Galactic diffuse emission modelled by the GALPROP software includes the contributions from the inverse Compton (IC) scattering off soft high-energy electrons, as well as the neutral pion decay and non-thermal bremsstrahlung that take place in Hi and H2 regions. However, the contribution of non-thermal bremsstrahlung emission in passive clouds is expected to be relevant only below 100 MeV (e.g. Habicht et al. 2007), when the electron-to-proton ratio is $e/p > 0.1$. Considering the typical estimated ratio of $e/p \sim 0.01$ as determined in observations of cosmic ray abundances at Earth (e.g. Hillas 2005), the bremsstrahlung contribution to the γ-ray emission can be safely neglected when modelling passive clouds. Thus we calculate background emission contributions only for IC using GALPROP(Vladimirov et al. 2011), which uses information regarding CR electrons and interstellar radiation field (ISRF). Isotropic templates related to the CR contamination and extragalactic γ-ray background are also included in our analysis. To derive the neutral pion decay γ-ray emission, we used templates generated from dust opacity maps derived by the Planck collaboration (Planck Collaboration et al. 2011), where we assumed that γ-rays trace the spatial distribution of the molecular gas. It should be noted that the Planck maps have an angular resolution $< 0.1^\circ$ is better than, or similar to, the resolution of Fermi-LAT at all energies, so these maps may be used as templates in the Fermi-LAT analysis. For the purposes of our analysis we chose – as in Crocker et al. (2007) – to define the Sgr B region as $0.4^\circ < l < 0.9^\circ$, $-0.3^\circ < b < 0.2^\circ$ and have used the dust opacity maps for the following model:

Fig. 2. Images of residual γ-rays above 1 GeV obtained using (a) the standard Fermi diffuse background (gll_iem_v05_rev1.fit and iso_source_v05_rev1.txt) and (b) our dust and IC model templates, as discussed in the text.
Fig. 3. Spectral energy distribution of γ-ray from the Sgr B complex. The grey bands represent the error of the Fermi-LAT measurement and consist of both systematic and statistic errors. The stars (with associated errors) represent the diffuse γ-ray flux discovered by H.E.S.S. (Aharonian et al. 2006), and the dot-dashed line is the power law obtained using the photon index and normalisation obtained from the original H.E.S.S. paper reporting its discovery. The dotted line represents the predicted γ-ray spectrum obtained by assuming that the CR spectrum in the Sgr B region is the same as the local CR spectrum measured by PAMELA.

Summing all these effects, we found in the low energy bins that the systematic errors can be as large as 50%; however, above 2 GeV, the systematic errors are compatible with the statistical errors derived in the likelihood fitting. The error region taking into account both systematic and statistical errors is represented in Figure 3. We delayed the discussion of the error that the mass estimate of the complex introduces until Section 3.2, given that the mass does not have a bearing on the obtained γ-ray flux.

In addition to the resulting spectrum derived from the Fermi-LAT data from 0.1 GeV to 30 GeV, including the above-discussed errors, Figure 3 shows the data points for the diffuse TeV γ-rays observed by the H.E.S.S. telescope (Aharonian et al. 2006). Also shown in this Figure is the spectrum of the predicted γ-rays obtained by assuming that the CR density in the Sgr B region is the same as PAMELA measurements. We used the proton spectrum calculated by PAMELA and the $p-p$ collision cross-section parametrisation of Kafexhiu et al. (2014) to calculate the predicted γ-ray spectrum. For the calculation, we assumed the total mass of the gas to be $1.5 \times 10^7$ $M_\odot$ (as discussed below) and used an enhancement factor of 1.79, as suggested by Kafexhiu et al. (2014), to account for the contribution from heavy nuclei. It should be noted that the PAMELA measurement suffered from solar modulation at low energies (mainly $E < 10$ GeV, see e.g. in Adriani et al. 2013). Thus the calculated γ-ray flux should be less than the prediction obtained using a demodulated CR spectrum. However, the uncertainties in the observed γ-ray spectrum below 1 GeV are significant, which may hinder any exact determination of the CR spectrum in this energy range. Therefore, for simplicity we do not consider the demodulation models here for simplicity. As Figure 3 shows, at low (below 1 GeV) and high energies (above 10 GeV), the measured γ-ray flux is compatible with flux predicted using a local, solar-modulated CR spectrum (i.e. the PAMELA observations), whilst at intermediate energy ranges (e.g. 1–10 GeV) there is a slight excess in the measured flux, compared to what is seen locally. This could be interpreted as the result of the presence of low-energy proton sources inside the Sgr B region. It should also be mentioned that because the PAMELA observation suffered from solar modulation in this energy range, the excess cannot reflect the true deviation between the CR density we measured and the local, demodulated CR density. Also plotted in Figure 3 are the H.E.S.S. data points (Aharonian et al. 2006), which reveal a much harder spectrum and
higher absolute flux compared with the \textit{Fermi-LAT} data, implying a different origin for the VHE \(\gamma\)-ray emission.

3.2. The gas content of the Sgr B region

A major assumption in this work is that the majority of the \(\gamma\)-ray emission is produced by neutral pion decay brought about by the interaction of the CR protons with the ambient molecular material of the Sgr B complex. Thus a major component in the error of the CR proton flux of the Sgr B region (see below) is its mass. Here we derive a mass estimate based on the \textit{Planck} dust opacity maps and compare it to mass estimates for the region contained in the literature.

The CS(1–0) survey of the GC using the Nobeyama 45 m telescope by Tsuibo et al. (1999) determined the mass of the Sgr B complex (over a similar area to the one used here) to be \(0.6 \sim 1.5 \times 10^7 \, M_\odot\). In this estimate, there is some uncertainty about the total gas mass of the region, since the CS(1–0) traces only very dense (\(10^4 \, \text{cm}^{-3}\)) gas, and CO(1–0) emission, which traces lower density gas, cannot assist for both optical depth reasons and the freezing-out onto dust grains (Walsh et al. 2011). Indeed, even the robust ammonia molecule may suffer from self-absorption towards the cores of Sgr B2 (Ott et al. 2014). However, other independent estimates of the total mass, as well as the major constituents of the complex, allow us to constrain the possible range of values as much as possible. Indeed, an upper limit on the mass of the Sgr B complex is the mass estimate of the central molecular zone (CMZ), the structure of which the Sgr B complex is a subset. Using a range of difference tracers, Dahmen et al. (1998) determine this mass to be \(3 \times 10^7 \, M_\odot\). The \textit{Herschel} satellite also determined a mass with the 100-pc ring that it discovered of \(3 \times 10^7 \, M_\odot\) (Molinari et al. 2011). Together, these (larger structure) estimates place a firm upper limit of \(\sim 3 \times 10^7 \, M_\odot\) above which the Sgr B complex cannot exceed. On the other hand, the mass of the individual component, Sgr B2, is \(> 6 \times 10^4 \, M_\odot\) (Jones et al. 2008), and a crude estimate for the Sgr B1 cloud is \(\sim 4.5 \times 10^5 \, M_\odot\) (Mehringer et al. 1992). However, Tanaka et al. (2009) found at least \(5 \times 10^4 \pm 30\% \, M_\odot\) of material in a shocked region within Sgr B1. Thus a combined Sgr B1 and B2 mass of \(\sim 10^7 \, M_\odot\) and implying an uncertainty of a factor of about \(\sim 2\) seems more than reasonable.

3.3. Sgr B Mass from the \textit{Planck} dust opacity maps

To derive the CR (proton) flux from \(\gamma\)-rays, one requires an accurate estimate of the mass, \(M\), and distance, \(d\), for the \(\gamma\)-ray emission region. As an additional cross check for the mass estimates discussed above, we have also obtained an estimate of the Sgr B complex mass using the \textit{Planck} dust opacity map shown in Figure 1 (Right). To do this, we used a formula that relates the dust opacity and the column density using the dust as the reference emissivity according to Equation 4 of (Planck Collaboration et al. 2011):

\[ \tau_M(\lambda) = \left( \frac{\tau_D(\lambda)}{N_H} \right)^{\text{dust}} [N_H + 2X_{CO} W_{CO}] , \]

where \(\tau_M\) is the dust opacity as a function of the wavelength, \(\lambda\), \((\tau_D/N_H)^{\text{dust}}\) the reference dust emissivity measured in low-\(N_H\) regions, \(W_{CO}\) the integrated brightness temperature of the CO emission, and \(X_{CO} = N_{HI}/W_{CO}\) the \(H_2/CO\) conversion factor.

\[ \text{For our analysis, we fixed the distance to the Sgr B complex to 8 kpc.} \]

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|c|c|}
\hline
\(\phi(E)\, \text{[erg s}^{-1} \text{cm}^{-2}]\) & 10^{-10} & 10^{-11} & 10^{-12} & 10^{-13} & 10^{-14} \\
\hline
\(\text{Energy (MeV)}\) & 1000 & 10000 \\
\hline
\end{tabular}
\caption{Spectrum of different components of \(\gamma\)-ray emission from the Sgr B region. The (red) crosses represent the IC component, whilst the (blue) stars represent the isotropic component, both with associated errors shown. The (black) plus signs are the total observed \(\gamma\)-ray component from the region.}
\end{table}
Substituting the last into Equation 1 above, one obtains
\[ N_H = N_{\text{HI}} + N_{\text{H}_2} = \frac{1}{2} \tau_m(A) \left( \frac{\tau_D(A)}{N_H} \right)^{\text{dust}}^{-1}. \] (2)

In our analysis we use a dust emissivity at 353 GHz of \( \tau_{\text{dust}} = 1.18 \pm 0.17 \times 10^{-26} \) cm\(^2\), obtained from Table 3 of Planck Collaboration et al. (2011). Thus, the total (dust-derived) mass of a cloud is
\[ M_d = m_{\text{H}} N_H A_{\text{cl}} \approx m_{\text{H}} \tau_D \left( \frac{\tau_D}{N_H} \right) \Omega_d d_{\text{pc}} \approx 2.72 \times 10^8 d_{\text{pc}}^{-1} \int \tau_d d\Omega \left[ \text{M}_\odot \right], \] (3)

where \( m_{\text{H}} \) is the mass of the hydrogen atom, \( A_{\text{cl}} \) and \( \Omega_d \) refer to the clouds’ physical and angular area, respectively, \( d_{\text{pc}} \) is the distance of the cloud in kpc, and \( \int \tau_d d\Omega \) the optical depth of the dust integrated over the angular extent of the cloud in units of arcminutes\(^2\).

From this, we derive a dust mass for the entire Sgr B complex (as defined above) of \( 1.5 \pm 0.2 \times 10^7 \text{ M}_\odot \), which is consistent with the masses derived from various methods above. Given that the mass estimate derived above is derived from the dust opacity map, which is the dust emissivity integrated over the entire line of sight, then it is no surprise that our estimate reach the upper end of the CS(1–0) mass estimate. On the other hand, Molinari et al. (2011) used low-dust-opacity regions within the 100-pc ring region to obtain an estimate of the total dust mass from this region alone (i.e. without contamination from dust in between us and the GC, as well as behind it). From a total mass, integrated along the line of sight, of \( \sim 4 \times 10^7 \text{ M}_\odot \), they estimated a total 100-pc-gas-ring mass of \( 3 \times 10^7 \text{ M}_\odot \), which is about 75% of the total mass. From our calculation above, 75% of this is \( 1 \times 10^7 \text{ M}_\odot \), which is very close to the values found by molecular line emission studies. In line with the fact that the Sgr B complex contains Sgr B2, the most massive and active star-forming region in the Galaxy (Jones et al. 2008), this suggests that our mass estimate is dominated purely by the material located in the GC. However, even given the above, we still consider our estimate to be an upper limit, since this places a conservative upper limit on the CR proton flux in this region.

3.4. CR proton spectrum from the Sgr B C complex

We have obtained an estimate of the proton spectrum in the Sgr B complex. This was done using the \( \gamma \)-ray observations and the parametrisation of the neutral pion decay broad band \( \gamma \)-ray spectrum introduced by Kafexhiu et al. (2014). The parametrisation of the cross section in Kafexhiu et al. (2014) possesses an accuracy of about 10%. Further uncertainties may rise owing to the differences in each simulation program discussed there and may amount to 20% in the energy range in which we are interested. Both uncertainties are much smaller than the uncertainties in the mass estimation. Detailed discussions of these uncertainties are beyond the scope of this paper, and in the calculation below we stick to the parametrisation of Kafexhiu et al. (2014) based on the GEANT 4 code at low energies and the PYTHIA 8.1 code at high energies. Given the turnover in the \( \gamma \)-ray flux spectrum shown in Figure 3, we have, in our procedure, assumed a proton
spectrum to be in the form of a broken power law:

$$\psi(E_p) = N(E_p + E_{bk})^{-\gamma},$$

where $E_p$ is the proton kinetic energy, $E_{bk}$ corresponds to the break energy, and $\gamma$ is the power-law index. Using a $\chi^2$ fitting routine, we find best-fit parameters for the above spectrum of $\gamma = 3.1 \pm 0.3$ and $E_{bk} = 4.5 \pm 2.0$ GeV with $\chi^2/d.o.f = 2.5/8 = 0.3$.

Figure 5 shows the results of our fitting procedure. We show the results using a mass for the Sgr B complex of $1.5 \times 10^5$ $M_\odot$, with the shaded region representing the 1$\sigma$ error of the fitting routine. The off-white region shows an additional part of the allowed flux-energy phase-space obtained by allowing the mass of the Sgr B region to vary within the errors of the mass estimates (conservatively, $0.6 - 1.5 \times 10^5$ $M_\odot$; c.f. Section 3.2). The crosses show the spectrum resulting from fitting the PAMELA proton spectrum measurement at the top of the Earth’s atmosphere, whilst the hatched region illustrates the CR proton spectrum derived by Yang et al. (2014) for the nearby (500 pc) Orion B GMC. We can see that the proton fluxes derived here vary from 1.05–4 times that of the local CR proton flux.

Considering the large uncertainties in both the measurement systematics and mass estimates, this flux is rather close to the local value. Additionally, the proton index of $\gamma = -3.1 \pm 0.3$ is very steep, considering that the large-scale distribution of TeV $\gamma$-rays possesses a very flat spectrum of $\gamma = -2.29 \pm 0.27$ (Aharonian et al. 2006). The break energy of $E_{bk} = 4.5 \pm 2.0$ GeV is consistent with those seen in other molecular clouds and can be ascribed to propagation effects of lower-energy CR protons presumably because of being unable to penetrate the dense regions of GMCs (Yang et al. 2014).

4. Conclusions

We have presented new analysis of five-years worth of Fermi-LAT data. Our analysis was motivated by fundamental, unanswered questions about the level of the CR sea in different parts of the Galaxy. Whilst nearby clouds have been closely studied, owing to their high $M_d/d^2$ parameter, clouds that are farther away are tougher for obtaining robust $\gamma$-ray data. The GMC complex of Sgr B represents our best chance of observing the CR-sea at a distant point in the Galaxy, owing to its $M_d/d^2$ value of $10^5$, despite it being located in the GC, at a distance of ∼8 kpc.

We have used the 350 GHz dust opacity maps from the Planck satellite to obtain an independent mass estimate for the Sgr B complex of $1.5 \pm 0.2 \times 10^5$ $M_\odot$. This agrees well with independent (and varied) molecular-line estimates of the complex as a whole, as well as with molecular-line estimates from individual components within the Sgr B complex. However, we do note that, because the dust opacity is a measure of the total dust emissivity along the line of sight, we still consider the derived mass estimate to be an upper limit.

While the observed $\gamma$-ray spectrum at high energies (above 10 GeV) is compatible with the gamma-ray spectrum calculated for the local cosmic ray spectrum measured, for example, by PAMELA at low energies, we observe some excess in the detected $\gamma$-ray flux at lower energies, up to a factor of two. This is very different from observations of the diffuse $\gamma$-ray emission of the Galactic Ridge by H.E.S.S. in the TeV domain, where the energy spectrum is much harder, and the flux is significantly higher than the one expected from interactions of the sea of galactic cosmic ray. The slight excess of $\gamma$-ray flux at sub-10 GeV energies may reflect the solar modulation effects of the PAMELA measurement. Otherwise, it can also be explained either by the presence of low-energy particle accelerators in the Galactic centre or by effects related to the change of the character of propagation of cosmic rays (e.g. slower diffusion) of the the galactic cosmic rays in the region of the Galactic centre. But, in either case, it is likely that the gamma-ray flux reported in this paper, at least its highest energy part, traces the sea of galactic cosmic rays.
