(Dated: October 5, 2015)

Entanglement drives nearly all proposed quantum information technologies. The suppression of the uncertainty in joint quadrature measurements below the level of vacuum fluctuations is a signature of non-classical correlations. Entangling frequency modes of optical fields has attracted increased attention in recent years, as a quantum network would rely on interfacing light at telecommunication wavelengths with matter-based quantum memories that are addressable at visible wavelengths. By up-converting part of a 1550 nm squeezed vacuum state to 532 nm, we demonstrate the generation and complete characterization of strong continuous-variable entanglement between widely separated frequencies. Non-classical correlations were observed in joint quadrature measurements of the 1550 nm and 532 nm fields, showing a maximum noise suppression 5.5 dB below vacuum. A spectrum was measured to demonstrate over 3 dB noise suppression up to 20 MHz measurement frequency. Our versatile technique combines strong non-classical correlations, large bandwidth and, in principle, the ability to entangle the telecommunication wavelength of 1550 nm with any optical wavelength, making this approach highly relevant to emerging proposals for quantum communication and computing.

I. INTRODUCTION

There has been continuous interest in investigating long-range quantum information networks, for reasons both fundamental [1] and applied [2]. Due to extremely long coherence times, and the relative ease with which they can be manipulated, optical modes are commonly considered to be the best means of distributing entanglement over large distances. Established fiber-optic technology offers relatively high transmission efficiency for wavelengths in the telecommunication band around 1550 nm, where scattering and absorption rates leading to photon loss are minimal.

A true quantum information network would incorporate a number of nodes, where quantum states could be stored and even processed. These nodes could generally take the form of single atoms [3], atomic ensembles [4, 5] or solid-state systems [6, 7]. This implies that the reversible mapping of quantum states between optical and material modes will necessarily be ubiquitous in quantum networks. As almost all current quantum memories operate at visible wavelengths, an efficient interface between entangled optical modes at telecommunication and visible wavelengths is a key capability to demonstrate.

A conceptual scheme of an elementary quantum link between two nodes of a quantum network is illustrated in Fig. 1. A source emits two optical beams at telecommunication wavelength prepared in an entangled twomode squeezed vacuum state, and each beam is sent to one node of the quantum network. To enable efficient interfacing with quantum memories, the transmitted light beams are frequency up-converted, and their quantum state is stored in quantum memories [8] for further processing. This schematic can represent, e.g., an elementary segment of a quantum repeater [9–11], where efficient transmission of light over short distances would be combined with local processing of stored quantum states, entanglement distillation and entanglement swapping, to efficiently establish quantum correlations over arbitrarily large distances.

FIG. 1. (Color online) Conceptual schematic of an elementary segment of a quantum network where entangled light beams establish quantum correlations between two nodes of the network. Efficient transmission of light is ensured by operating at telecommunication wavelength, and the coupling to local quantum memories (QM) is enabled by frequency up-conversion (SFG) of the transmitted light beams.
Previous work has demonstrated the interface between telecommunication and visible wavelengths with entangled single photons [12]. In contrast to this discrete-variable (DV) encoding of quantum information, we focus on an interface for continuous-variables (CV), which is more general, as the states are not restricted to a limited Hilbert space. The main advantage of CV encoding is that it allows for deterministic quantum operations [13–15], and benefits from well-established measurement techniques such as balanced homodyne detection. There have been several demonstrations of quantum memories for CV states [16–20] and the classical benchmark for memory fidelity has been experimentally surpassed using displaced two-mode squeezed states [4].

Here we deal with a broadband two-mode squeezed vacuum state which represents a fundamental resource for CV quantum information processing [21]. We demonstrate and characterize frequency up-conversion of one half of this state from 1550 nm to 532 nm, and we verify that the quantum conversion preserves the modes’ broadband entanglement. It has been previously demonstrated that CV entanglement can span optical frequencies one octave apart [22]. However, no “on the fly” wavelength conversion has yet been achieved. States with non-classical characteristics over a broad frequency range are particularly interesting for channel multiplexing to achieve higher density information encoding [27], as well as for time-frequency domain CV quantum computing protocols [24]. Our modular “on the fly” approach is versatile and can be modified to entangle 1550 nm light not only with 532 nm but with any other optical wavelength.

II. EXPERIMENTAL SETUP AND RESULTS

Our proof-of-principle demonstration of a versatile continuous variable entanglement interface is based on the efficient frequency up-conversion of one part of a broadband two-mode squeezed vacuum state of light. The schematic of the experimental setup can be found in Fig. 2. First, squeezed vacuum states of light at 1550 nm are produced by cavity-enhanced degenerate type I optical parametric down-conversion, also called optical parametric amplification (OPA). The squeezing bandwidth is determined by the cavity bandwidth. The squeezed states are subsequently mixed with the vacuum mode at a variable beam splitter (VBS), to generate entanglement between the reflected and transmitted mode [20]. The transmitted mode is mode-matched to the sum-frequency generation cavity (SFG), which is pumped with a strong coherent field at 810 nm. In the SFG the 1550 nm signal field is up-converted to 532 nm, while its quantum properties are maintained [24–28]. The up-converted mode is analyzed at a balanced homodyne detector (BHD) utilizing a local oscillator at 532 nm. A local oscillator at 1550 nm is used to analyze the reflected mode of the VBS at a second BHD. Further details about the various components of the setup can be found in [23–25, 29, 30].

The entanglement of the two light beams at 532 nm and 1550 nm can be conveniently characterized by the quantity $\mathcal{I}$, introduced by Duan et al. [31],

$$\mathcal{I} = \text{Var}[\hat{X}_{1550} + \hat{X}_{532}] + \text{Var}[\hat{P}_{1550} - \hat{P}_{532}],$$

where $\hat{X}_\lambda$ and $\hat{P}_\lambda$ denote the amplitude and phase quadratures, respectively, of an optical beam at wavelength $\lambda$. The quadrature variances are normalized such that $\text{Var}[\hat{X}] = \text{Var}[\hat{P}] = 1$ for vacuum, and $\mathcal{I} < 4$ certifies the presence of entanglement of the two beams [31].

The variances of linear combinations of quadratures appearing in Eq. (1) characterize correlations between individual modes of a two-mode quantum state. A simple theoretical model yields

$$\text{Var}[\hat{X}_{1550} + \hat{X}_{532}] = 2 - (1 - V_-)(t r_{532} - r t_{1550})^2,$$

$$\text{Var}[\hat{P}_{1550} - \hat{P}_{532}] = 2 + (V_+ - 1)(t r_{532} - r t_{1550})^2.$$

approximately 90%. In contrast, the mode at 1550 nm has less
the photo diodes at 532 nm, both of which were approx-
ciency, as well as the non-perfect quantum efficiency of
of the squeezed input state to the entanglement interface
marginally different beam splitter tuning [32]. In our ex-
minimum value of
V
is attained at a

difference of the phase quadrature amplitudes \( \hat{P}_{1550} - \hat{P}_{532} \). This is achieved when \( t_{532} = t_{1550} \), and in this case the variance of the difference in phase quadratures reaches the vacuum noise level, \( \text{Var}[\hat{P}_{1550} - \hat{P}_{532}] = 2 \), see point D in Fig. 3. Within the error bars of our experiment, this setting also provides the strongest Gaussian entanglement as quantified by \( \mathcal{I} \). Indeed, it follows from Eq. (2) that, for this setting, entanglement is certified and \( \mathcal{I} < 4 \) whenever the input state is squeezed and \( V_- < 1 \). A more detailed theoretical analysis, however, reveals that the minimum value of \( \mathcal{I} \) is attained at a marginally different beam splitter tuning [32]. In our experiment, the variable beam splitter sent a larger fraction of the squeezed input state to the entanglement interface to compensate for the non-perfect SPG conversion efficiency, as well as the non-perfect quantum efficiency of the photo diodes at 532 nm, both of which were approximately 90%. In contrast, the mode at 1550 nm has less downstream losses, on the order of 12%, dominated by the visibility of the balanced homodyne detector.

The sum of the two BHD outputs is analyzed in a spec-
trum analyzer, providing noise powers of joint quadrature amplitudes that are proportional to the joint operator variances, over a range of sideband frequencies. A zero span measurement of the revealed correlations at a side-

FIG. 3. (Color online) Characterization of our unconditional quantum interface. Shown is the sum of the two BHD signals at 5 MHz sideband frequency. While the phase \( \phi \) of the BHD at 532 nm was continuously scanned, the phase of the BHD at 1550 nm was set to measure the squeezed quadrature amplitude \( \hat{X}_{1550} \) (ii, red trace) or anti-squeezed \( \hat{P}_{1550} \) quadrature (i, blue). The four extremal points represent the following measurement settings: A: \( \text{Var}[\hat{X}_{1550} + \hat{X}_{532}] \), B: \( \text{Var}[\hat{X}_{1550} - \hat{X}_{532}] \), C: \( \text{Var}[\hat{P}_{1550} + \hat{P}_{532}] \), D: \( \text{Var}[\hat{P}_{1550} - \hat{P}_{532}] \). The orange trace (iv) was recorded when the 532 nm phase was also fixed, revealing stable non-classical correlations about 5.5 dB below the vacuum level (iii, black). Note that the traces were recorded successively, and there is no actual meaning in the relative positions of the minima and maxima. None of the traces was corrected for our detection scheme’s dark noise (v, gray).

To analyze the spectral properties of the correlations, the frequency dependence of the sum signal was measured and is shown in Fig. 4. Therefore, the phase of the 1550 nm field was set to measure the squeezed (red trace) or anti-squeezed (blue) quadrature while the 532 nm phase was set to measure the minimum noise in the sum signal. More than 3 dB of correlations below the vacuum noise are measured up to a sideband frequency of about 20 MHz.

III. CONCLUSION

In conclusion, we present an entanglement-preserving interface for multi-color quantum optical networks. Our
result demonstrates that current techniques in nonlinear optics enable the efficient frequency conversion of half of an entangled two-mode state. As a proof-of-principle, we up-converted from the near-infrared to the green spectrum, producing CV entanglement between continuous-wave light fields at 1550 nm and 532 nm. Up to 5.5 dB of nonclassical correlations with a bandwidth of about 20 MHz were maintained during the conversion process. The bandwidth can be increased by widening the cavity linewidths, and the strength of the nonclassical correlations can be further improved by reducing optical loss due to imperfect PIN photo diodes, cavity mode matchings and absorption in nonlinear crystals. We consider our work to be an important building block for future multicolor quantum networks, which may further include CV as well as DV concepts.

IV. ACKNOWLEDGMENT

We thank Geoff Pryde and Vitus Händchen for useful discussions.
