ABSTRACT: Nanowires hold great promise as tools for probing and interacting with various molecular and biological systems. Their unique geometrical properties (typically 100 nm in diameter and a few micrometers in length) enable minimally invasive interactions with living cells, so that electrical signals or forces can be monitored. All such experiments require in situ high-resolution imaging to provide context. While there is a clear need to extend visualization capabilities to the nanoscale, no suitable super-resolution far-field photoluminescence microscopy of extended semiconductor emitters has been described. Here, we report that ground state depletion (GSD) nanoscopy resolves heterostructured semiconductor nanowires formed by alternating GaP/GaInP segments ("barcodes") at a 5-fold resolution enhancement over confocal imaging. We quantify the resolution and contrast dependence on the dimensions of GaInP photoluminescence segments and illustrate the effects by imaging different nanowire barcode geometries. The far-red excitation wavelength (~700 nm) and low excitation power (~3 mW) make GSD nanoscopy attractive for imaging semiconductor structures in biological applications.

KEYWORDS: Nanowires, microscopy, super-resolution imaging, photoluminescence, semiconductor heterostructures

High aspect ratio nanostructures such as nanowires (NWs) or nanotubes can be utilized as sensors or needles to measure and perturb the surface or interior of a cell.¹⁻³ These structures, owing to their geometry and optoelectronic properties, are candidates for new-generation nanometer-sized probes for biological molecules, including enzyme or other protein recognition,⁴⁻⁶ analysis of electrical activity,⁷,⁸ long-term molecular tracking,⁹ intracellular delivery,¹⁰,¹¹ cellular force measurements,¹² or nerve tissue engineering.¹³,¹⁴ All of these applications are to date still hampered by our relatively poor understanding of how extrinsic materials and their topology influence cell properties.¹⁵,¹⁶

To fully exploit the potential of one-dimensional nanostructures in biological research, it is necessary to establish minimally invasive, simple optical methods that allow controlled measurements of their interactions with cells. The high degree of control over NW synthesis enables the fine-tuning of their geometrical and optoelectronic properties, which makes NWs perfect model structures in this respect. Several studies have examined the interactions of NWs with cells, mainly using confocal microscopy. NWs have been indirectly visualized as dark spots due to spatial exclusion within labeled cells¹⁷,¹⁸ or were directly labeled with fluorescent organic dyes.¹⁹⁻²¹ To circumvent bleaching issues associated with these methods, it has been recently proposed²² to use the intrinsic photoluminescence of NW heterostructures as contrast method for their visualization in biological systems.²²,²³ However, the diffraction-limited resolution of conventional lens-based microscopy restricts the amount of information that can be extracted from such images. While imaging at higher resolution, scanning electron microscopy (SEM) only provides surface information, and reduces throughput in the case of slice-and-view SEM techniques. Therefore, there is a need for methods allowing for optical imaging of photoluminescent nanowires at resolution below the diffraction limit.

Addressing the resolution problem, a variety of subdiffraction far-field microscopy (here in short, "nanoscopy") methods have been reported for organic fluorophores, photoswitchable fluorescent proteins, quantum dots, and color centers in diamond. Breaking the far-field diffraction barrier ultimately relies on judiciously exploiting intrinsic emitter properties and transferring emitters between (at least) two states (typically signaling "on" and non-signaling "off") to achieve their separation²⁴,²⁵ at subdiffraction length scales. In far-field nanoscopy, the properties of the accessible intrinsic states determine the best choice of imaging approach and its

Figure 1. Properties of heterostructured nanowires. (a) Schematic drawing of a barcode nanowire and SEM image. Red lines indicate the photoluminescent GaInP segments. (b) Band structure diagram for GaP and GaInP. (c) Photoluminescence spectrum of a single NW GaInP segment. (d) Photoluminescence lifetime measured at room temperature with instrument response function (IRF, $\tau_{\text{jitter}} = 40$ ps) shown in gray. The estimated photoluminescence lifetime after deconvolution was $\tau_x \approx 10 \text{ ps}$.

Most popular far-field nanoscopy methods are not readily applicable to semiconductor nanowires. The coordinate-stochastic approaches (e.g., PALM\textsuperscript{26,27}/STORM\textsuperscript{28}) rely on temporal signal intermittencies (blinking) of individual emitters, cannot be applied to the NWs due to the constant background PL contributions from many excitons within an extended segment. Alternatively, inhibiting short-lifetime photoluminescence by a coordinate-targeted strategy like STED\textsuperscript{29} is challenged by unwanted absorption of the de-excitation light. Thus, as NWs feature high photostability, a different strategy appeared promising: to control the transfer of electrons to the conduction band (“on” state, Figure 1b) in a coordinate-targeted manner, transferring electrons out of the valence band “off” state, as originally suggested in the classic ground state depletion (GSD) concept\textsuperscript{30-32} and later also used in saturated structured illumination microscopy (SSIM).\textsuperscript{33,34}

The majority of carriers are thus forced to reside most of the time in the “on” state by using an excitation intensity distribution in the focal plane featuring one or even many zeros. Upon scanning, this leads to the acquisition of a “negative” image with subdiffraction resolution. Excitation and photoluminescence are ideally disallowed at the zero(s), that is, the targeted coordinate(s). Everywhere else, the transition out of the ground state is guaranteed, and signal is generated.

Designating the two electron states as “on” and “off”, electron transfer to the “on” state and thus photoluminescence can be virtually guaranteed for excitation intensities $I \gg \frac{\hbar \nu}{\tau_x \sigma_{\text{exc}}} \approx I_\nu$ where $\hbar \nu$ is the photon energy, $\sigma_{\text{exc}}$ is the excitation cross-section, $\tau_x$ is the photoluminescence lifetime and $I_\nu$ denotes a characteristic threshold intensity at which half of the maximal PL signal $\eta$ is elicited. The estimated fraction of electrons in the “on” state scales with $I$ as follows: $\eta \approx I / \left(1 + \frac{\eta}{I_\nu}\right)$. The effective point spread function (PSF), which governs resolution, can therefore be described by $h_{\text{eff}}(x) \approx \frac{1}{1 + \frac{\eta}{I_\nu}}$, where $I(x)$ is the spatial distribution of a doughnut-shaped excitation beam, which can be approximated around the targeted coordinate as $I(x) \approx I_{\text{max}} \left(\frac{x^2}{\Delta d^2} + \zeta\right)$. In this expression, $\Delta d$ is related to the resolution of the diffraction-limited optical system, and $\zeta$ is the relative depth of the excitation beam minimum ($\zeta \ll 1$). The resolution, defined here as the full width at half-maximum (FWHM) of the registered intensity dip, in the GSD microscope is well...
Figure 2. Resolution increase in GSD photoluminescence nanoscopy for a nanowire with a single GaInP segment. (a) Saturation behavior of the GaInP photoluminescence signal \( \eta \). The saturation power is \( P_s = 0.322 \, \text{mW} \) (corresponding to a peak threshold intensity \( I_s \approx 400 \, \text{MW/cm}^2 \)). The blue arrow indicates abrupt, irreversible decreases in photoluminescence with three subsequent measurements at 7 mW shown. Error bars indicate standard deviations of maximal signal from several adjacent line profiles. (b) Resolution scaling \( \Delta d_{\text{GSD}} \) as a function of the excitation power. The resolution was defined as the full width at half-maximum (FWHM) of the signal dip. Experimental data and fits to the shown expressions are displayed in (a) and (b) (including a finite offset related to the physical segment diameter in b). Error bars indicate standard deviations from several adjacent line profiles. (c) Scattering (gray) and photoluminescence (red) signal from a single NW. Scale bars: 500 nm. (d) Photoluminescence intensity profiles showing resolution changes as a function of the excitation power.

approximated by \( \Delta d_{\text{GSD}} \approx \Delta d \left( \frac{I}{I_s} \right)^{1/3} + \zeta \) and tends to very small values for increasing intensity. In practice, the resolution is limited by the material properties and the residual intensity in the doughnut minimum (details in Supporting Information).

We found that, despite the short exciton lifetime of several picoseconds, it is possible to shelve electrons in the “on” state and ensure the PL of GaInP (Figure 2a). We imaged NWs that contained a single GaInP segment to characterize the signal \( \eta \) and the resolution \( \Delta d_{\text{GSD}} \) as a function of excitation power. All experiments were performed on a home-built GSD microscope with short excitation pulses (~5 ps in the focal plane) in time-gated operation (Supporting Information). On the basis of experimental data (Figure 2a), we inferred a peak threshold intensity \( I_s \approx 400 \, \text{MW/cm}^2 \). Having identified the PL properties of GaInP (Figures 1 and 2a), the resolution of the imaging system was significantly improved by adopting a doughnut-shaped excitation beam (Figure 2b–d). For the excitation wavelength \( \lambda = 700 \, \text{nm} \), the resolution was improved to values comparable to the GaInP segment size (~50 nm). PL intensity profiles orthogonal to the NW axis (Figure 2d), that is, across the narrow dimension (labeled as \( y \)), were used to estimate the resolution scaling with excitation power (Figure 2b,d). Note that our measurements were carried out with a single NW width of ~50 nm (and this offset was taken into account in the fitting analysis), meaning that resolution will not tend to zero for very large powers. In addition, the dip of the doughnut-shaped profile is narrower in FWHM than a Gaussian-like standard excitation profile for the same wavelength (compare Figures 2b and 3g). Occasionally, we observed a permanent reduction of the PL signal (to a lower PL level, or even complete loss of signal) starting at powers of ~3–7 mW (for example, the arrow in Figure 2a). The PL reduction was often accompanied by an increased contrast of the registered minimum (Figure S6).

Next, we proceeded to explore the imaging of barcode NWs22 (Figures 3–5). We imaged NWs that were synthesized to have a diameter of ~20 nm and consisted of four GaInP PL segments (233 ± 40 nm length) separated by nonluminescent GaP segments (164 ± 21 nm), as characterized by SEM. Figure 3a–c provides example confocal and GSD image comparisons. The confocal microscopy mode (Figure 3a) did not resolve individual segments, even after the application of deconvolution algorithms incorporating the known PSF (Figure 3d). GSD nanoscopy (Figure 3b,c,e) clearly distinguished the four segments. We retrieved a more intuitive image representation (Figure 3c) by simple subtraction of the raw data from its low-frequency counterpart (obtained by low-pass filtering in the frequency domain to remove high-resolution information; see Supporting Information). In principle, the corresponding confocal data can also be used to provide the reference image for subtraction. On the basis of this image (Figure 3c), the lengths of the GaP and GaInP segments appeared as 162 ± 20 nm and 225 ± 11 nm, respectively, in an intensity profile along the NW axis (Figure 3f). The direction labeled \( x \); lengths were measured as FWHMs based on spacings of maxima and minima; standard deviations from \( n = 12 \) and 9 segments, respectively). Providing a convenient target to estimate the resolution on the thinnest spatial feature, the intensity profile across the NW, that is, orthogonal to the NW axis (Figure 3g,
direction labeled $y$) was reduced from $388 \pm 25$ nm in confocal mode to $76 \pm 11$ nm in GSD ($n = 12$). The inferred resolution enhancement by 5-fold therefore closely matches the modeled PSF of $\sim 66$ nm at 5 mW (details in Supporting Information section "Limitations of direct subdiffraction imaging with GSD").

Moving to shorter and more closely spaced GaInP segments (Figure 4), we imaged NWs whose segment dimensions were characterized using SEM to $64 \pm 15$ nm/50 $\pm 20$ nm for GaInP/GaP lengths, respectively, with a diameter $\phi = 43 \pm 3$ nm (Supporting Information, "Specification of NWs" section). The relatively large uncertainties for the segment length measurements are due to low contrast between GaP/GaInP segments in SEM images, as well as possible differences across the population of NWs related to the growth procedure. GSD nanoscopy resolved individual luminescent segments (Figure 4b–d) with an average separation of their centers of $112 \pm 13$ nm ($n = 20$ segments; SEM, $114 \pm 5$ nm $n = 32$ segments). Post-deconvolution (Figure 4d,f), we characterized the segment lengths to be $66 \pm 10$ nm/50 $\pm 16$ nm (GaInP/GaP, $n \geq 15$), observing an excellent agreement with the SEM measurements. While contrast was high ($>0.8$) for an isolated segment (Figure 2c,d), multiple closely spaced segments were imaged at significantly reduced contrast (<0.22). For the nanowires of Figure 4, we found that the contrast continuously decreased between adjacent GaInP segments along a nanowire (compare enlarged views in Figure 4e), possibly related to a gradation in inherent photoluminescence strength.35 The GaInP segment with the lowest photoluminescence corresponds to the first grown segment.22 Moreover, in GaInP nanowires, reduced contrast can arise from differences in material composition...
along the length of the nanowires, which affect the intensity, as previously described.$^{22,36}$

Modeling of the GSD image formation revealed a clear connection of image contrast with the PL segment length and diameter (Figure 4h), with highest contrasts for shortest and thinnest PL segments. In addition, small spacings between segments lead to decreased contrast (Figure 4i). Therefore, the observed contrast enhancement upon the sudden decrease in PL signal (Figure S6) suggests a volume reduction of the emissive GaInP segment. As size and spacing strongly affect contrast, there is clearly room for optimization in the design of heterostructures to increase the quality of images, keeping in mind that smaller PL volumes come with reduced signals.

Figure 5 displays further data on 40 nm diameter NWs with short luminescent segments (50 ± 8 nm), this time with ∼2 times longer GaP spacers (95 ± 13 nm). The contrast along the NWs increased from 0.10 for the nanowires in Figure 4 to 0.14 for the nanowires in Figure 5 (data not shown). We compared the GSD nanoscopy characterization of the nanowires to SEM images (Figure 5c–h) and found an excellent agreement in the segment diameters $\langle \Delta y \rangle$, lengths $\langle \Delta x \rangle$, and separations $\langle \Delta x_c \rangle$, extracted using both methods (data tabulated in Figure 5).
In summary, we have demonstrated experimentally that GSD nanoscopy resolves GaP/GaInP NW heterostructures with diameters down to 20 nm at a 5-fold resolution enhancement compared to confocal microscopy. GaP/GaInP NWs with even smaller diameters (10 nm) became challenging to image due to significant emission intermittency. As the diameter of NWs approached the exciton size (GaInP ∼4−10 nm), the PL showed strong fluctuations (Figure S5 in Supporting Information), making segment positions virtually impossible to extract. We note that PL fluctuations can be possibly controlled37,38 by choosing the PL material, notably through exciton-size or core−shell engineering to protect surface excitons. However, the nature of signal intermittencies would not allow the direct application of a PALM/STORM/GSDIM strategy:26−28,39 Excitons from an individual segment cannot be made to emit together while keeping the neighboring segment “silent”, because the electrons behave independently and cannot be “locked” into one of the two states for an extended time. Even if selection (“activation”) at the single-exciton level were realized (e.g., by very low fluxes of excitation photons), the exciton would not deliver bursts of ≫1 consecutive photons, which is a fundamental requirement to allow the localization of one entity (here, the segment).

Further, it is worth commenting on a relevant difference between methods that prepare the “on” state at the targeted coordinate(s) (“positive” imaging) and those “inverted” approaches, as applied here, which locally single out the “off” state (“negative” imaging). In both cases, coordinates are targeted by positioning a zero or zeros (minimum/a) of the state-switching light intensity. In “positive” imaging, signals...
from the locally prepared “on”-state features are not affected by any contributions from neighboring non-targeted features because these are in an “off” state. But the “negative”-imaging modalities, forcing the emissive “on” state everywhere except at the zero(s), suffer from the problem of collecting signal from the entire diffraction zone. This includes contributions from all nearby features, whose signals fill up the all-important dip in registered intensity, partially hampering super-resolution information in the presence of noise. Note that the limitation does not stem from an imperfect state preparation. The “negative” modality is just as efficient in generating the “on”−“off” state contrast in the specimen as the “positive” modality, but the readout/detection step is less favorable in terms of contrast. The effect of reduced contrast in the presence of nearby emitters was previously appreciable in GSD nanoscopy data recorded from nitrogen vacancy (NV) color centers, that is, confined point-like emitters in diamond.32 In the extended semiconductor structures investigated here, we showed that shorter PL segments lead to higher contrast, as do larger separations from the nearest luminescent neighbors. Certainly, the ability to freely control the geometry within NW heterostructures (notably, the sequence of PL segment lengths and spacings) allows for further optimization. Another possible direction for improvements will be controlled changes in the NW segments’ material composition. This would allow for the modification of spectral characteristics (even customized differences among adjacent PL segments) as well as saturation behaviors and damage thresholds. The latter remains a limiting factor to additional resolution improvements, and a better understanding of the mechanisms of PL loss will benefit future advances.

Because of the far-red excitation wavelength (low phototoxicity) and the moderate average power, we believe the described approach will be highly relevant for revealing positions, orientations, and identities of NWs in biological contexts. Membranes or other cellular structures could be visualized by complementary nanoscale imaging methods such as STED. The good performance of NW GSD nanoscopy at room temperature indicates similar applicability at physiological contexts.
