Using state-of-the-art first-principles calculations we study the magnetic behavior of CeFeAs. We find the Ce layer moments oriented perpendicular to those of the Fe layers. An analysis of incommensurate magnetic structures reveals that the Ce-Ce magnetic coupling is rather weak with, however, a strong Fe-Fe and Fe-Ce coupling. Comparison of the origin of the tetragonal to orthorhombic structural distortion in CeFeAs and LaFeAs shows marked differences; in CeFeAs the distortion is stabilized by a lowering of spectral weight at the Fermi level, while in LaFeAs by increase in Fe spin moment. Finally, we investigate the impact of electron doping upon CeFeAs and LaFeAs and show that (a) while in CeFeAs the ground-state Fe moment remains largely unchanged by doping, the stability of magnetic order goes to zero at a doping that corresponds well to the vanishing of the Néel temperature and, (b) in contrast the LaFeAs system remains magnetic with a slowly vanishing moment as a function of doping.

I. INTRODUCTION

The recently discovered family of FeAs-based compounds that, upon electron doping, become superconducting with transition temperatures up to 55 K, are attracting a lot of interest. Structurally these materials ROFeAs (R=La, Ce, Pr, Nd, and Sm) are very similar in that they are formed from FeAs layers separated by rare earth or lanthanide oxide layers. In striking contrast to the well-known cuprates, these FeAs layers are magnetic metals with small itinerant moment, in contrast to the well-known cuprates, these FeAs layers are magnetic metals with small itinerant moment,

In particular, at the onset of superconductivity the moment on the Fe atoms vanishes, and a key question concerns the possible role of such spin fluctuations in the superconducting transition.3,4

Despite the diverse set of rare-earth and lanthanide atoms involved in these materials, physically they share many similarities. In particular, (i) at temperatures around ~150 K a structural phase transition from tetragonal to orthorhombic crystal symmetry occurs, (ii) this is then closely followed by a magnetic phase transition to a spin order antiferromagnetic (AFM) in nature, (iii) upon doping with fluorine the AFM order is suppressed and superconductivity appears. Furthermore, calculations reveal that (iv) the nonmagnetic Fermi surfaces are all strongly nested,3,5,6 and (v) that the moment of the Fe atoms depends critically upon the separation of the Fe layer from the adjacent As layer.5,7,8

Given the diversity of constituents involved in this class of materials, such uniformity of behavior appears, at first sight, somewhat surprising. The question then arises if the underlying physical mechanisms behind such phenomenon as the structural distortion or doping behavior are also the same. In the present work we investigate this by analyzing the properties of CeFeAs as compared to the well-studied LaFeAs. The choice of these two materials is motivated by the fact that among the rare-earth and lanthanide oxyni-
ensures convergence of the second-variational step as well as the convergence with respect to the \( k \) points. All the experimental lattice parameters for CeOFeAs are from Ref. 14 and for LaOFeAs from Ref. 21

### III. GROUND STATE FOR UNDOPED UNDISTORTED CeOFeAs

We first consider the undistorted undoped ground state of CeOFeAs. One of the most striking aspects of the theoretically intensively studied compound LaOFeAs has been the spread of results for magnetic properties, attributed to both an unusual sensitivity to the approximation to exchange correlation, and a sensitive dependence upon the separation of the Fe and As layers, \( z_{\text{As}} \).\(^5\)\(^7\)\(^8\) This latter behavior is also found in the case of CeOFeAs,\(^22\) however, in contrast to LaOFeAs a spin-polarized generalized gradient approximation (GGA) (Ref. 23) calculation yields an optimized \( z_{\text{As}} \) in near perfect agreement with experiment, see Fig. 1. Given this choice of \( z_{\text{As}} \) we now determine the ground-state magnetic structure for undoped undistorted CeOFeAs. In order to study the possible incommensurate spin structures we have calculated the total energy as a function of the spin-spiral vector \( \mathbf{q} \), for various directions in the Brillouin zone (BZ), using the local-spin-density approximation (LSDA).\(^24\) For the in-plane spin spirals, going in the direction \([0.5, 0.5, 0]\) to \([1, 1, 0]\), we find a clear sharp minimum at the commensurate \( \mathbf{q} \) vector of \([0.5, 0.5, 0]\), equivalent to stripe AFM spin configuration (top panel Fig. 2). From Fig. 2 it is also clear that the various spin configurations are almost degenerate in the direction \([0.5, 0.5, 0.4]\) to \([0.5, 0.5, 0.5]\). This is indicative of weak interplane coupling [coupling between one Fe(Ce) layer with the next Fe(Ce) layer]; this finding is concomitant with experimental results of Zhao et al.\(^14\) This is a good news as far as the computational effort is concerned since this would mean that it is not essential to double the unit cell in \( c \) axis for collinear calculations. Experimentally\(^14\) it is known that below a temperature of 4 K the Ce moments couple strongly to the Fe moments, interestingly, we also find this to be the case (all present calculations are performed at 0 K). Indications of this reasonably strong magnetic coupling between Fe and Ce atoms are; (a) a small change (1%) of the Ce moment (performed with a fixed spin calculation), leads to a large change (3%) in the Fe moment and (b) to change Fe moment by 1.3% (Ce moment kept fixed to zero) requires 7 meV energy, while similar change in Fe moment with Ce atoms treated magnetically requires larger (11 meV) energy. This extra cost in energy in the later case is due to the localized nature of the Ce moments which via magnetic coupling tries to preserve the moment on the Fe atoms. This mechanism is local in that we find similar behavior for several different long-range orders of the Ce sublattice (ferromagnetic, as well as several different spin-spiral vectors). Such a weak dependence on the nature of the long-range order suggests that also for disordered spin arrangements similar behavior will be seen, an important point since at all temperatures of interest the Ce sublattice will have substantial spin disorder.

In addition to the LSDA functional, the use of GGA and LSDA+U functionals (with \( U=6 \) eV and \( J=1 \) eV for the Ce atom), also leads to the Fe layer adopting the stripe AFM structure found in all the oxypnictides, with the magnetic moments of the Ce layer perpendicular to those of the Fe layer. The Fe (Ce) moments are found to be \( 1.58 \mu_B \) (0.56\( \mu_B \)), \( 1.52 \mu_B \) (0.92\( \mu_B \)), and \( 1.30 \mu_B \) (0.54\( \mu_B \)) for the LSDA, LSDA+U, and GGA functionals, respectively, with the corresponding experimental values 0.94\( \mu_B \) for Fe and 0.83\( \mu_B \) for Ce. The agreement with experiment for the Fe moment is thus rather poor for all functionals considered. This may be attributed to the exceptionally sensitive dependence of the Fe moment on \( z_{\text{As}} \), see Fig. 1, which for CeOFeAs is even more pronounced than in LaOFeAs. It is also worth mentioning that the moments listed above are spin moments and the orbital contributions, which require the presence of spin-orbit coupling in the Hamiltonian, are not added. Since in the present work main focus is on the possible incommensurate nature of spins all the calculations are...
performed using fully noncollinear spin-spiral formalism which can only be treated in absence of spin-orbit coupling.

Turning now to the spin-spiral moments (lower two panels Fig. 2), we find that the moment remains almost unchanged upon changing the magnetic structure away from the stripe AFM spin configuration. This is in striking contrast to LaOFeAs, which remains spin polarized\(^{25,26}\) only in a small region about the \(M\) point, \([0.5, 0.5, 0]\), with the moment vanishing elsewhere in the BZ. Since for CeOFeAs the moment on the Fe atoms changes only slightly\(^{−5.2\%}\) upon moving across the BZ hence the role of spin fluctuations could be rather different in these two materials. This difference may be understood as a consequence of the nature of the various interplane and intraplane magnetic couplings in CeOFeAs. In particular, the intraplane coupling of the Ce atoms is very weak—we find the energy difference between FM- and AFM-ordered in-plane Ce moments to be almost degenerate with, additionally, the magnitude of the Ce moments unchanged by the choice of FM or AFM order. Thus the nature of the Ce-Ce interaction results in the Ce moment remaining unchanged by a spin-wave configuration; this in turn acts to preserve the Fe moment due to the relatively strong interplane Fe-Fe coupling. This weak Ce-Fe coupling has yet another consequence; in order to study this system using a collinear formalism one does not need to construct a supercell in order to account for, the experimentally observed, different spin-spiral \( \mathbf{q} \) vectors for the Ce and the Fe layers. At this point it is important to mention that these conclusions remain unchanged for all three exchange-correlation functionals (LSDA, GGA, and LSDA + \( \mathcal{U} \)) used in the present work; despite the functional the ground state is AFM stripelike and among the magnetic atoms the strongest coupling is between intraplane Fe-Fe atoms followed by interplane Fe-Ce atoms. The intraplane Ce-Ce and indirect interplane coupling between Fe-Fe and Ce-Ce atoms always remain very weak.

IV. STRUCTURAL DISTORTION IN CeOFeAs VS LaOFeAs

As with all the oxypnictides, CeOFeAs undergoes a structural phase transition from tetragonal to orthorhombic crystal symmetry,\(^{14}\) which in this compound occurs at 160 K. In order to determine the physical reason behind this transition we have performed \textit{ab initio} LSDA calculations. As may be seen in Fig. 3 the nonmagnetic compound does not show any crystal distortion, but upon performing spin-polarized calculations one finds a minimum at a distortion angle of 90.30\(^{o}\) (for definition of distortion angle see Refs. 8 and 17). This clearly shows that the magnetic interactions between Fe atoms lead to structural distortion. This is hardly surprising; the ground states for the undistorted CeOFeAs (AFM stripelike) is essentially magnetically frustrated, and one means of removal of the magnetic frustration is the structural distortion.

Thus both the distortion angle and critical temperature for CeOFeAs are very similar to those found in LaOFeAs, however, as we will now show, the underlying reason for the lowering in energy due to distortion is entirely different in the two cases. In the case of LaOFeAs the crystal distortion leads to removal of magnetic frustration\(^{17,18}\) which in turn leads to an increase in moment on the Fe atoms. This increase in moment causes a gain in magnetization energy which is then sufficient to make the distorted structure energetically preferred.\(^{5}\) On the other hand, the moment of both the Fe and Ce atoms remains essentially unchanged in CeOFeAs upon distortion, see right-hand panels of Fig. 3. The reason for this lies again in the magnetic coupling between the Fe and Ce atoms; the moment on the Ce atom does not depend strongly upon the distortion angle due to weak intraplane Ce-Ce coupling, this in turn preserves moment on the Fe atoms. The consequence of this is that the gain in magnetization energy is not sufficient to make the distorted structure favorable. However, a careful analysis of various contributions to the total energy (one-electron, electrostatic, exchange correlation, and magnetization) exhibits that all but the one-electron kinetic energy show a monotonic behavior as a function of the distortion angle. The one-electron energy of CeOFeAs shows a clear minimum at 90.30\(^{o}\) while (lower-left panel Fig. 3), in dramatic contrast, the LaOFeAs one-electron kinetic energy monotonically increases as a function of distortion angle. This points to the one-electron energies playing a leading role in the structural distortion of CeOFeAs. Recently, a similar mechanism was found in the case of BaFe\(_2\)As\(_2\), where it was shown that the relevant physics with respect to structural distortion in oxypnictides lies in the one-electron energies.\(^{27}\)

Since this striking contrast between LaOFeAs and CeOFeAs is linked to the one-electron energies this difference should also be apparent in the electronic band structure of the two materials. In this regard in Fig. 4 are shown the nonmagnetic as well as magnetic (AFM stripe phase) density of states (DOS) for the undistorted and distorted lattices of CeOFeAs and LaOFeAs. One feature common to both compounds is that, as one would expect, spin polarization results in a large shift of spectral weight away from the Fermi level. Turning to the impact of distortion one observes a striking difference: in LaOFeAs there is a substantial \textit{increase} in spectral weight at the Fermi level. This increase in the spectral weight upon distortion has been noticed before in Refs. 17 and 28. In contrast to this, in CeOFeAs spectral weight

---

moves away from the Fermi level. This scenario is similar to
the one observed in the case of BaFe$_2$As$_2$. Clearly,
therefore, although both the distortion angle and transition
temperatures are very similar in these two oxypnictides, the ori-
gin of the structural phase transitions is very different. At this
point it is also worth mentioning that heat-capacity measure-
ments of McGuire et al. showed that this decrease in the
DOS at the Fermi level in CeOFeAs on distortion is consis-
tent with the Seebeck coefficient measurements.

V. MAGNETISM IN ELECTRON-DOPED
LaOFeAs VS CeOFeAs

The most important property of the iron oxypnictides is
the occurrence of a superconducting phase transition at a
critical electron doping. An interesting difference be-
tween the temperature-doping phase diagrams of
CeO$_{1-x}$Fe$_2$As and LaO$_{1-x}$Fe$_2$As is that, for the former
case, the Néel temperature of the magnetic phase goes con-
tinuously to zero as critical doping is approached ($x_c =$0.06), while in LaO$_{1-x}$Fe$_2$As one instead finds a sharp
drop in the Néel temperature at a critical doping of
$x_c=0.045$ (see right-hand panel Fig. 6). Concomitantly,
low-temperature measurements of the magnetic order of the Fe
layer in CeO$_{1-x}$Fe$_2$As show that it is entirely lost before $x_c$
(left panel Fig. 6). The situation is slightly different for
LaO$_{1-x}$Fe$_2$As in that, experimentally it is established that
beyond $x=0.075$ no magnetic order persists, however, if
magnetic order is entirely lost before the superconducting
transition is still a point of discussion. An important
question for understanding the role of magnetism in the su-
perconducting transition is then whether it is the moment of
the Fe atoms that vanishes, or whether it is simply the stripe
AFM order that vanishes.

To investigate this issue we calculate CeO$_{1-x}$Fe$_2$As and
LaO$_{1-x}$Fe$_2$As by deploying the virtual crystal approxima-
tion (VCA). Although the VCA neglects much of the physics
of disorder, it has been shown recently to provide a surpris-
ingly accurate account of magnetism and Fermiology in
LaO$_{1-x}$Fe$_2$As. In order to determine the impact of the ap-
proximation to the $xc$ functional, calculations are performed
using the LSDA, LSDA+$U$, and GGA functionals. The experimental data are
taken from Ref. 21

We first consider the overall behavior of the magnetic
moment with doping for LaO$_{1-x}$Fe$_2$As. This is shown in
Fig. 5 for GGA and LSDA+$U$, and two different parameter-
zations, von-Barth-Hedin (vBH) (Ref. 35) and Perdew-Wang$^{24}$ of the LSDA. It is immediately apparent
that the small moment of this system, simply leads to a scaling
of the doping curve but the over all behavior remains the
same; like in experiments, the change in moment is very
small for $x<0.05$, i.e., less than the critical doping. How-
ever, a marked divergence between experiment and theory
occurs after this point; while the theoretical data show a
slowly vanishing tail the experimental data display a sudden
decrease. Our calculations, therefore, imply that magnetic
and superconducting order are competing ground states in
the sense that magnetism does not die before the onset of
superconductivity. The sharp decrease in moment at $x=0.05$
may then be brought about by the onset of superconductivity.
The question of whether magnetism and superconductivity
then coexist for a small doping range, or if the onset of
superconductivity destroys entirely the magnetic order, can-
not be answered without explicitly treating superconductivity
within the same framework. At this point one should also
note that the small moment itinerant magnetism of this sys-
tem implies a strong role for spin fluctuations which is
not correctly treated by the (semi)local functionals used in
the present calculations. These fluctuations may also act to
damp the slowly vanishing tail of the moment vs doping seen
in Fig. 5.

Similar calculations for CeO$_{1-x}$Fe$_2$As (left panel Fig. 6)
show that there is almost no change in the Fe moment upon
doping. This behavior is totally different from that of
LaO$_{1-x}$Fe$_2$As and is in apparent contradiction to the expe-
mental data. The reason for this again lies in the magnetic
coupling between the Ce and Fe atoms; localized Ce mo-
ments are not affected by small doping in the FeAs plane and

FIG. 4. (Color online) Density of states calculated using the
LSDA for undistorted nonmagnetic, undistorted magnetic, and
distorted magnetic structures for CeOFeAs and LaOFeAs. Stripe
antiferromagnetic order was used for the magnetic calculations.

FIG. 5. (Color online) Moment per Fe atom (in $\mu_B$) as a func-
tion of doping calculated using two different parameterizations of
LSDA, LSDA+$U$, and GGA functionals. The experimental data are
taken from Ref. 21
reasonably strong coupling between Ce and Fe moments then leads to very small change in Fe moments as a function of doping. However, if we consider the magnetization energy, i.e., the quantity $E_{\text{non-mag}} - E_{\text{mag}}$ (right panel Fig. 6), this falls sharply at exactly the critical doping $x_c = 0.06$. Thus it is the stability of the magnetic order which is reduced upon doping, not the actual Fe moment. This sudden reduction in stability, which is not found in LaOFeAs, could be the reason behind the differing forms of the Néel temperature phase boundary in these two compounds.

For the case of LaOFeAs, it is evident from recent experiments\cite{21} that there exists a complex structural and magnetic behavior with doping, the full nature of which has yet to be clarified. In fact, on the question of whether the distortion observed at $x=0$ persists beyond the superconducting transition at $x = 0.05$, the current experimental data are contradictory; Refs. 21 and 32 find that distortion persists up to $x = 0.08$, while in Refs. 10 and 12 no distortion is observed beyond the onset of superconductivity at $x = 0.05$. The magnetic state of LaO$_{1-x}$FeAs is also uncertain, with one experiment\cite{21} finding evidence of an incommensurate structure for $x > 0$. In order to clarify this situation we have determined the ground state for several doping concentrations, by minimizing over both the distortion angle $\gamma$ and spiral vector $\mathbf{q}$. Our major findings are (see Fig. 7); (a) up to a doping of $x = 0.08$ distorted crystal, with distortion angle $\gamma = 90.2^\circ$, is lowest in energy.\cite{36} (b) Beyond the doping of $x = 0.08$ the system again prefers to be in a tetragonal ground state (with $\gamma = 90^\circ$). These results are in agreement with the experimental findings.\cite{11,21} (c) Subsequent minimization of the spin spiral $\mathbf{q}$ reveals a stripe phase to incommensurate spin-spiral transition ($\mathbf{q} = [0.54, 0.54, 0]$) at a doping of $x = 0.04$. This finding is in agreement with the experimental evidence of Huang et al.\cite{21} We should note, however, that the small energy difference between the incommensurate and

38 For these calculations corresponding experimental lattice parameters from Refs. 11 and 21 are used. It is worth noting that on the use of undoped experimental lattice parameter, for the theoretical calculations of the doped LaOFeAs, an erroneous distortion in the opposite direction (y<90) is obtained.
