(Rceived 10 January 2009; published 26 May 2009)

Surface electronic structure of polycrystalline and single-crystalline samples of the half-metallic ferromagnet Co$_3$Sn$_2$S$_2$ was studied by means of angle-resolved and core-level photoemissions. The experiments were performed in temperature regimes both above and below a Curie temperature of 176.9 K. The spectroscopic results are compared to local-spin density approximation band-structure calculations for the bulk samples. It is found that the surface sensitive experimental data are generally reproduced by the bulk computation suggesting that the theoretically predicted half-metallic properties of Co$_3$Sn$_2$S$_2$ are retained at the surface.

I. INTRODUCTION

The concept of “half-metallic ferromagnetism” was introduced by de Groot et al.$^1$ for Heusler phases that are considered to be highly relevant for spin-dependent manipulation of charge carriers.$^2$ Spin-polarized band-structure calculations for NiMnSb reveal metallic properties for the spin-majority electrons while the spin-minority states possess a band gap at the Fermi energy ($E_F$). These theoretical predictions were, however, controversially inspected by spectroscopic experiments. While only 50% spin polarization of the Fermi-energy electrons was measured by spin-resolved photoemission (PE),$^3$ a spin-resolved inverse PE study shows that the polarization at $E_F$ can approach 100%.$^4$ The obtained discrepancy was explained by possible segregation phenomena that may lead to considerable deviations of the surface as compared to bulk stoichiometry.$^3,5$ On the other hand, due to reduced coordination even stoichiometric surfaces may exhibit an electronic structure that is very different compared to the bulk.$^6$ But driven by miniaturization of electronic devices, in particular electronic structure at the surface as probed by spectroscopic techniques became of highest importance for applications.

A half-metallic ferromagnetic behavior was recently predicted by Weihrich and Anusca$^7$ for the shandite Co$_3$Sn$_2$S$_2$. The term shandite will be used in this paper for all compounds isostructural to Ni$_3$Pb$_2$S$_2$. From band-structure calculations they found that a ferromagnetic transition in this compound is accompanied by the formation of a band gap in the spin-minority direction. Since the Fermi level lies within this gap, Co$_3$Sn$_2$S$_2$, which is metallic in nonmagnetic state, becomes insulating for spin-minority states at a Curie temperature ($T_C$) of 176.9 K.$^8$ From a classification given by Coey and Venkatesan$^9$ Co$_3$Sn$_2$S$_2$ can be assigned to type I$_A$ half-metallic ferromagnets.

Measurements of magnetic susceptibility$^8,10$ confirm the results of the bulk band-structure calculation. It was found that the ferromagnetism in Co$_3$Sn$_2$S$_2$ is rather sensitive to structural deviations as demonstrated by substituting Co by Ni. Only a few percent of Ni impurities decrease rapidly the $T_C$ in (Co$_{1-x}$Ni$_x$)$_3$Sn$_2$S$_2$. Above $x=0.2$ the compound is no more ferromagnetic.$^{10}$ This experimental finding is in accordance with band-structure calculations performed for Ni$_3$Sn$_2$S$_2$ by Weihrich et al.$^{11}$ In this shandite, the energy gap in exchange-split transition-metal $3d$ states is shifted to higher binding energy (BE) as compared to its position in Co$_3$Sn$_2$S$_2$. Thus, the transition to ferromagnetism is suppressed. Another important issue reported in Ref. 7 is the influence of Sn and S atoms on electronic properties of (Co$_{1-x}$Ni$_x$)$_3$Sn$_2$S$_2$. Although Sn and S originating contributions to valence-band (VB) density of states (DOS) are negligible, particularly S-Sn-S bonds along (111) direction of the crystals are of high importance for the gap formation.

In this contribution we focus on surface electronic structure of Co$_3$Sn$_2$S$_2$. Experimental results measured by means of angle-resolved and core-level PE for single crystals, both above and below $T_C$, are compared with the corresponding data taken for polycrystalline samples. The spectroscopic results are compared to the local-spin density approximation (LSDA) bulk band-structure calculations performed for the nonmagnetic and ferromagnetic configurations. It is found that the rather surface sensitive experimental data are generally reproduced by the bulk computation. An enhancement of the Fermi-energy signal measured below $T_C$ is in accordance with the predicted magnetic band splitting resulting in a downward energy shift of the spin-majority bands that were unoccupied in the nonmagnetic sample. Spin-polarized spectroscopic experiments are necessary to quantify expected spin polarization of the Fermi-energy electrons in the surface region of Co$_3$Sn$_2$S$_2$.

II. EXPERIMENTAL AND THEORETICAL DETAILS

A. Samples

Stoichiometric single crystals have been grown by a modified vertical Bridgman technique. For this purpose polycrystalline Co$_3$Sn$_2$S$_2$ was placed in a tipped glassy carbon...
crucible. The crucible was inserted into a tantalum tube which was closed by an arg welding. Synthesis and handling steps were carried out in an argon gas box system ($p_{O_2}$, $p_{H_2}$). The closed tantalum tube was then sealed under vacuum in a quartz tube which was suspended by a Kanthal thread from the top to the hot zone of a resistance heated vertical tube furnace. The sample was slowly heated up to 1000 °C, kept there for 6 h, and slowly cooled within 72 h to 800 °C. After these steps the furnace was turned off and the samples were cooled down to ambient temperature. The crystal was removed from the glassy carbon crucible by careful mechanical fragmentation of the crucible. The grown crystals of typical lengths of 10 and 1 cm in diameter were cut, polished, and inspected by optical metallography. They were found to contain several large grains which could be mechanically separated. The chemical composition was checked by energy dispersive x-ray analysis. The lattice parameters which were obtained from refinement of powder x-ray diffraction data of a crushed piece of the crystal are in agreement with the literature.12

B. Photoelectron spectroscopy

High-resolution angle-resolved and core-level PE studies were carried out at the Berliner Elektronenspeicherring für Synchrotronstrahlung (BESSY) (beamline UE112-PGM-1) and in the laboratory of the Dresden University of Technology. The measurements were performed in ultrahigh-vacuum systems consisting of two distinct chambers for preparation and analysis. The PE spectra ($hv=21.2$, 40.8, 70, 200, 880, and 1486.6 eV [Al Kα]) were recorded with 180° hemispherical electron-energy analyzers (PHOBOS 150 at BESSY and Scienta 2002 in the laboratory) with energy resolution of 150 and 400 meV at full width at half maximum (FWHM) in the photon-energy region below 200 and above 880 eV, respectively. The angle-resolved PE data in the region of the Fermi energy were analyzed applying deconvolution with a Gaussian accounting for the finite experimental resolution. The measured S 2p core-level PE spectra were simulated exploiting the WINFIT program.13 PE peaks originating from S atoms in different chemical environments were least squares fitted with Voigt-shaped subspectra superimposed by a steeplike integral background.

The analyzers were fixed while the vertically positioned Co$_3$Sn$_2$S$_2$ samples were rotated, changing the incidence angle of photons as well as the polar angle of emitted photoelectrons. In order to get clean sample surfaces as necessary for PE experiments, the single-crystalline species were cleaved in situ by means of ceramic or metallic sticks glued at the crystal surfaces in a vacuum better than $3 \times 10^{-10}$ mbar. The polycrystalline samples were scraped with a diamond file at a pressure better than $8 \times 10^{-10}$ mbar. Base pressure during the measurements was always in the range of $1 \times 10^{-10}$ mbar. The samples were studied at room temperature and 40 K, which is above and below $T_C$.

Surface contaminations were monitored by tracing C and O 1s core-level signals in photoemission spectra of the species. The Fermi-level energy position of the analyzers were calibrated applying copper polycrystalline foils in electrical contact with the samples.

C. Band-structure calculations

Band-structure calculations were performed using the full-potential local-orbital minimum basis code FPLO (version 5.00–19, Ref. 14) within the local-spin density approximation. In the scalar relativistic calculation the exchange and correlation potential of Perdew and Wang15 was employed. A basis set was constructed from a combination of Co 3s and 3p, and Sn 3s, 4p, and 4d semicore states as well as Co 4s, 4p, and 4d, Sn 5s, 5p, and 5d, and S 3s, 3p, and 3d valence states. All lower lying states were treated fully relativistic as core states. The inclusion of the semicore states was forced by their non-negligible overlap due to the large extension of their wave functions. The formally unoccupied Sn 5d and S 3d states were included to improve the completeness of the basis set. The extension of the valence orbitals was controlled by an additional confining potential ($r/r_0$) with the parameter $r_0$ optimized with respect to the total energy.16 A dense mesh of 8000 k points in the Brillouin zone (BZ) has been applied to ensure accurate DOS and band-structure information. The calculations were carried out for the experimentally determined structural data (see next section).

III. RESULTS AND DISCUSSION

A. Sample characterization

1. Surface structure

The crystal structure of the shandite Co$_3$Sn$_2$S$_2$ is discussed in detail in Refs. 11 and 17. It is denoted by trigonal-rhombohedral symmetry of space-group 166 ($R\bar{3}m$), a lattice parameter $a=5.3754$ Å, and an axis angle of 59.91°. According to the trigonal axes, cobalt atoms occupy Wyckoff position 3e, tin atoms are placed in 1a and 1b, and sulfur atoms reside in position 2c with $z$(S)=0.216. The crystal structure of Co$_3$Sn$_2$S$_2$ is displayed in Fig. 1(a).

Owing to a quasi layered arrangement of atoms in Co$_3$Sn$_2$S$_2$, cleaved surfaces of measured single crystals are always perpendicular to [111] direction. Thus, three surface terminations are possible in the experiment: Sn atoms surrounded by either (i) six Co or (ii) six Sn atoms, and (iii) S atoms surrounded by six S atoms. Since all (111) planes mentioned above exhibit close-packed atomic structures, interpretation of PE spectra in terms of hexagonal symmetry, as indicated in Fig. 1(a), is justified.

The quality of the surface was checked by low energy electron diffraction (LEED). Obtained sharp images are displayed in Figs. 1(b)–1(d). The hexagonal structure of (111) surface becomes visible at 60 and 80 eV primary electron-energy energies. Thereby, the intensity of the LEED spots is strongly electron-energy modulated (compare to 50 eV pattern) as expected from the multiatomic basis of the crystal.

2. Core-level photoemission

To characterize electronic properties of the single-crystalline Co$_3$Sn$_2$S$_2$ samples, first a series of their core lev-
compound \( \text{Ni}_2\text{Sn}_2\text{S}_2 \), the electronic configuration \((\text{Ni}^{2+})_3[(\text{Sn}^{2+})_2\text{S}_4]^{2-}\) was derived from Mößbauer and core-level PE experiments.\(^{18}\) Note that the charge of the \( S^{2-} \) ions is completely compensated by the Sn atoms while the Ni atoms remain neutral.

Indeed \( S^{2-} \) configuration in \( \text{Co}_3\text{Sn}_2\text{S}_2 \) is confirmed by measured BE of 162.46 eV for the S 2p state \[ \text{main component in Figs. 2(a) and 2(b)} \]. In \( \text{Co}_3\text{Sn}_2\text{S}_2 \), the core level is slightly shifted toward lower binding energy compared to \( \text{Ni}_2\text{Sn}_2\text{S}_2 \) (162.8 eV).\(^{18}\) This shift is not related to an ionic bonding caused by possible charge transfer from the transition metal to the sulfur. Co may provide one 3d valence electron less than Ni and, therefore, the charge density on the sulfur site is expected to be larger in \( \text{Ni}_2\text{Sn}_2\text{S}_2 \). Thus, the covalent bonding, accompanied by a decrease in the bond length \((\text{Ni-S}: 2.191 \ \text{Å}, \text{Co-S}: 2.178 \ \text{Å})\) or different screening of the PE core-hole excitation might cause the observed BE behavior. A similar situation is encountered in transition-metal pyrites. When going from Co(S) to Ni(S)\(^{2-}\) the binding energy of the S 2p core level is increased by 0.1 eV.\(^{19}\) This fact supports the above conclusion that particularly the interplay between the transition-metal and sulfur atoms is responsible for the observed BE variation. In CoS with a \( S^{2-} \) configuration the S 2p PE signal is found at 161.8 eV binding energy.\(^{20}\) Here, the S atom is coordinated by six Co atoms in a trigonal prismatic arrangement, contrary to antiprismatic configuration in \( \text{Co}_3\text{Sn}_2\text{S}_2 \).

Besides the main contribution to the S 2p spectra discussed above, which is related to the \( S^{2-} \) configuration, an additional weak component at 165.5 eV binding energy is found for the polycrystalline samples \[ \text{see Fig. 2(a)} \]. According to Ref. 21 this component stems from \( S^0 \) atoms and can be assigned to nonstoichiometric sulfur. For the single-crystalline species, S 2p spectra reveal fine structure due to well-resolved spin-orbit splitting that is smeared out in lower quality polycrystalline samples owing to chemically inequivalent positions of the S atoms. Apart from the main doublet subspectrum, a second doublet shifted by 0.7 eV to lower BE is monitored \[ \text{Fig. 2(b)} \]. This minor component is interpreted as a surface-derived contribution. The reduced coordination number at the surface causes band narrowing that, in accordance with our calculations, results in an increased density of electronic states immediately below the Fermi energy. The constraint that the solid has to be charge neutral leads then to the shift of surface component to lower binding energy. The fact that the bulk S subspectrum is characterized by much higher intensity evidences that the cleaved surface is in any case not primarily S terminated. It leaves mainly the (i) and (ii) possibilities for surface termination \[ \text{Fig. 1(e)} \]. Note that the \( S^0 \) atoms do not noticeably contribute to the PE intensity in Fig. 2(b) pointing at good quality of the single-crystalline \( \text{Co}_3\text{Sn}_2\text{S}_2 \) samples measured in the present study.

The binding energy of the Co 2p\(_{3/2}\) level was measured to be 778.4 eV for both polycrystalline and single-crystalline samples \[ \text{Figs. 2(c) and 2(d)} \]. This value is close to the ones observed in CoS \( (778.1 \ \text{eV}) \) and CoSe \( (778.3 \ \text{eV}) \), and would support a Co\(^{2+}\) valence state.\(^{19}\) In the cobalt lower valent CoSe compound, the Co 2p\(_{3/2}\) binding energy is 778.7 eV.\(^{22}\) However, the length of Co-S bonds in \( \text{Co}_3\text{Sn}_2\text{S}_2 \) indi-

FIG. 2. Core-level PE spectra measured for polycrystalline and single-crystalline samples. Results of the least-squares fit analysis are shown by thin lines underneath the S 2p spectra.
cates covalency. On the other hand, the observed peak separation of 15.1 eV between $2p_{3/2}$ and $2p_{1/2}$ states points at the metallic Co-Sn bonds, contrary to a separation of 16 eV in Co$_2$ compounds. Thus, although pure ionic bonding should be ruled out, the situation is not as clear as in Ni$_3$Sn$_2$S$_2$ and some charging of the Co atoms is expected.

Analyzing line shapes of the Co core-level spectra, no satellite structures as reported in Refs. 23 and 24 are observed. In these studies the satellite structures were assigned to atomiclike multiplets well known for correlated materials where PE core-hole interacts with partly filled localized shells of $d$ or $f$ electrons. This multiplet structure of the $2p_{3/2}$ core level ($\sim 778.0$ eV BE) was not observed in Co metal pointing at purely itinerant character of $3d$ electrons there. Our data show that also in Co$_3$Sn$_2$S$_2$ all valence states are rather extended which justifies our theoretical description of the electronic structure within the LSDA approach. We may assume that the satellite structure measured in Ref. 24 might be related to possible sample oxidation as discussed by Galtayires and Grimblot.

The line shape of the Co $2p$ core-level spectra measured for polycrystalline samples is clearly asymmetric with a tail extending in the region of low binding energies [see Fig. 2(c)]. This observation can be explained by photoelectrons scattered inelastically on impurities and grain boundaries and signals stemming from Co atoms occupying nonstoichiometric positions in Co$_3$Sn$_2$S$_2$ polycrystals. This asymmetry is strongly reduced in PE spectra measured for the high-quality single-crystalline species [Fig. 2(d)].

From the data obtained by $^{119}$Sn Mößbauer spectroscopy in Ref. 18 a valence state 2+ was concluded for the Sn atoms in Ni$_3$Sn$_2$S$_2$. Similar measurements done by Weirich et al. on Co$_3$Sn$_2$S$_2$ point at partly filled Sn 5s shells. In our PE measurements (not shown) the Sn 4d$_{5/2}$ peak in Co$_3$Sn$_2$S$_2$ was found at 24.6 eV BE. This energy lies in the range known for Sn chalcogenides (24.5–24.8 eV, Ref. 26) and deviates considerably from the value reported for elemental Sn (24.0 eV, Ref. 27). Oxidation of Sn would shift the 4d peak to higher binding energy by about 1.5 eV, as expected for Sn$^{2+}$ configuration. This is not observed in our study both for polycrystalline and single-crystalline samples. The same conclusion is obtained from Sn 3d$_{5/2}$ levels [Figs. 2(e) and 2(f)] measured at 485.45 eV BE, which is close to its value in the Sn monochalcogenides (485.7 eV in SnS and SnSe, and 485.6 eV in SnTe).

The results of the above core-level PE experiments prove the extraordinary quality of our single-crystalline samples that are highly suitable for angle-resolved PE studies of the electronic structure of Co$_3$Sn$_2$S$_2$ presented below.

B. Calculated band structure

In the present study, the band structure of Co$_3$Sn$_2$S$_2$ was calculated using the approach and the crystalline parameters as described above. The obtained theoretical data are in accordance with the previous calculations of Weirich and Anusca.

Our results both for the spin-resolved and spin-integrated band structures as well as for corresponding valence-band density of electronic states are shown in Fig. 3. An energy gap between 0.15 and 0.45 eV BE is seen in the nonspin-polarized calculation. The metallic character of Co$_3$Sn$_2$S$_2$ is driven by bands crossing the Fermi energy above this energy gap. In a spin-polarized calculation, these bands are split due to exchange interaction. The spin-minority subbands occur above the Fermi energy while the spin-majority ones shift toward higher binding energies. As a result, the compound becomes insulating for the spin-minority channel while it remains metallic for the spin-majority direction. The bands around the gap are formed predominantly by Co 3d states with a small admixture of Sn and S contributions. Noticeable 5s and 5p contributions from the Sn atoms lie between 5 and 7 eV binding energy. Sn 4d states are calculated at about 26 eV BE for both inequivalent positions of these atoms. The calculated magnetic moment is 1.0$\mu_B$ per f.u., an integer value as expected for half-metallic ferromagnets.

C. Valence-band photoemission

1. Angle-integrated experiments

Angle-integrated investigation of the VB electronic structure of Co$_3$Sn$_2$S$_2$ was performed by means of photoelectron spectroscopy with two different photon energies, $h\nu=21.2$ and 40.8 eV, in order to distinguish in PE signals the contributions of electronic states with different angular-momentum character. While at $h\nu=21.2$ eV cross sections of photoionization of Co 3d, and valence-band p states of Sn and S are characterized by similar values; at $h\nu=40.8$ eV the Co 3d states must cause much higher intensity. The obtained ex-
PHOTOEMISSION STUDY OF ELECTRONIC STRUCTURE...

experimental results are compared with our band-structure calculations applying the LSDA formalism.

Polycrystals reveal no specific surface orientation. Thus, in contrast to single crystals, photoemission of polycrystalline samples provides results that are averaged over different surfaces. Therefore for a given compound, surface specific line samples provides results that are averaged over different regions in the BZ. Additionally, variable light polarization should not cover as much momentum (k) space as the spectra obtained from the polycrystalline samples, and (ii) measurements at \( h\nu = 21.2 \) eV and 40.8 eV were performed on different samples in order to probe each time freshly prepared sample surfaces that became contaminated after acquisition of each particular spectrum. Thus, distinct surfaces in both single-crystalline measurements cannot be completely ruled out. This might be reflected by the appearance of a double-peak structure between 0.4 and 1.3 eV BE in Fig. 4 that is not found in Fig. 4(c) and is not present in the calculated DOS. Apart from this deviation and the finding that the main maxima of the experimental energy distribution curves lie closer to \( E_F \), the experimental data are in general agreement with the calculated DOS. The fact that the main PE peak is located in the close vicinity of the Fermi energy complicates experimental observation of the energy gap predicted by the theory. The gap between the main peak and the Fermi-energy shoulder can be inferred, however, even from the polycrystalline data, suggesting its formation is not due to only one particular surface termination.

2. Angle-resolved experiments

A detailed assignment of the calculated nonmagnetic band structure to the angle-resolved PE spectra of Co\( _3\)Sn\( _2\)S\( _2 \) taken above \( T_C \) at room temperature is given in Figs. 5 and 6. The theoretical bands (black and white dots) superimpose the experimental plots (color scale representation) in order to give an estimate for the width of the energy gap and the position of features appearing in the measurements. Three photon energies—21.2, 40.8, and 70 eV—were used to sample different regions in the BZ. Additionally, variable light polar-
Thereby the inner potential be attributed to a background of scattered electrons. In this BE toward the Fermi level. The signal remaining at lower edge of the gap. Electron correlations that are not accounted for in our study might be responsible for the observed discrepancies. In Fig. 6, features below 0.5 eV binding energy, and \( k \) =0.3, 0.8, and 1.0 Å\(^{-1}\), respectively, can be particularly well described by the theory. It should be admitted that, however, there are some experimental observations that cannot be fully understood based on our single-particle LSDA ground-state calculations and the free-electron-like final-state model. Namely, the measured energy gap is much smaller than the predicted one and additional PE signals appear above the lower edge of the gap. Electron correlations that are not accounted for in our study might be responsible for the observed discrepancies. Corresponding angle-resolved PE spectra taken with \( \hbar \nu =40.8 \) eV at \( T \sim 40 \) K in the range of energies up to 0.5 eV below \( E_F \) are depicted in Fig. 7(a). In Fig. 7(b) the momentum distribution of the PE intensity along the gray line [marked by arrow in Fig. 7(a)] is shown by open dots. In this independent of the region probed in the Brillouin zone. Instead, a detailed data inspection yields weak Fermi-energy intensity modulations at different \( k \). In order to increase the contrast, suffering from the low intensity at the Fermi level, the measured spectral line shapes were deconvoluted with a Gaussian accounting for the finite experimental resolution. By this procedure the Fermi-energy intensity modulations are emphasized and can be assigned to the Fermi-level crossings by the electronic bands that are predicted by our calculations (see Fig. 3).

Despite considerable surface sensitivity of the photoemission experiments, our study reveals good agreement between the measured data and the results of the bulk electronic structure calculations. This conclusion is similar to those drawn from photoemission investigations of high-temperature superconductors where bulk calculations were successfully used for angle-resolved data interpretation as well. This nontrivial finding might be related to the fact that the extended Bloch functions, which describe the bulk electronic states, penetrate with their trailing tails also in the surface region of solids and, therefore, can be probed in photoemission. In any case, the agreement between our experimental results and the calculations at room temperature make us confident to apply PE in order to verify changes in the electronic structure at \( E_F \) at temperatures below \( T_C \) (176.9 K) predicted by the theory (see Fig. 3).
plot the low-temperature $k_f$ distribution curve (open dots) is compared with the curve acquired at room temperature (solid dots). Since the main differences between results calculated for Co$_3$Sn$_2$S$_2$ with unpolarized and polarized spins are seen close to $E_F$ (Fig. 3), the experimental data in Fig. 7(b) were normalized with each point to the PE intensity of the corresponding energy distribution curve integrated between 0.5 and 5 eV BE.

A Fermi-energy signal enhancement at $k_F=0.95$ Å$^{-1}$ is clearly monitored in this figure. This result supports the scenario drawn up by our spin-resolved band-structure calculations. The spin degeneracy of the Fermi-energy bands that are predicted to stabilize the half-metallic ferromagnetism in Co$_3$Sn$_2$S$_2$ is lifted for $T< T_C$: the resulting spin-majority band is shifted far below $E_F$ causing the increase in PE intensity shown in Fig. 7.

IV. CONCLUSIONS

The electronic structure of polycrystalline and single-crystalline shandite Co$_3$Sn$_2$S$_2$ was studied by means of angle-resolved and core-level PE at temperatures below and above the Curie temperature. The experimental data are compared with the LSDA band-structure calculations carried out both for the spin-unpolarized and spin-polarized electronic configurations. It is shown that the rather surface sensitive experimental data are reproduced by the bulk computation. The growth of the $E_F$ signal measured below $T_C$ is explained by the lifting of the spin degeneracy at the Fermi level and shifting downward of the spin-majority bands that were unoccupied in the nonmagnetic case. Although our present spin-integrated data give strong evidence in favor of the half-ferromagnetic scenario, spin-resolved measurements are necessary to quantify the expected spin polarization of the electrons at the Fermi level in Co$_3$Sn$_2$S$_2$.
