Abstract

The bulk structure of copper in various binary Cu/ZnO catalysts for steam reforming of methanol under activation and working conditions is studied by in situ X-ray diffraction (XRD) and X-ray absorption spectroscopy (XAS). The evolution of bulk phases from CuO/ZnO precursors during activation with hydrogen was studied using temperature programmed reduction (TPR) (448 – 523 K, 2 vol-% H₂ with and without water vapor). With decreasing copper content the onset of reduction is shifted from 473 K (pure CuO) to 443 K (40 mol-% Cu) accompanied by a decrease in Cu crystallite sizes (from 210 Å to 40 Å). Using time-resolved in situ XANES measurements at the Cu K edge during TPR experiments the degree of reduction was monitored. It is shown that Cu(I) oxide forms prior to Cu. Adding oxygen to the feed gas leads to the formation of a mixture of Cu(II) and Cu(I) oxide accompanied by a complete loss of activity. After switching back to steam reforming conditions a higher activity is attained while the catalyst shows an increased Cu crystallite size (up to 40%). EXAFS measurements at the Cu K and the Zn K edge indicate a structural disorder of the Cu particles in the medium range order based on increasing Debye-Waller factors for higher Cu-Cu shells. Furthermore, the dissolution of Zn atoms (up to ~ 4 mol-%) in the copper lattice is detected. Upon oxidation/reduction cycles activity is increased, the disorder in the copper particles increases, and Zn segregates out of the copper bulk. A structural model is proposed which ascribes the enhanced activity to structurally disordered (strained) copper particles due to an improved interface interaction with ZnO.

Introduction

Cu/ZnO catalysts can be used to produce hydrogen by steam reforming of methanol with high selectivity and activity (1,2). Thus, methanol often is considered as an alternative "automotive" fuel and could serve as a potential hydrogen source for fuel cell applications (3). Current efforts are dedicated to the minimization of selectivity to CO which acts as a poison in fuel cell applications (4). The steam reforming reaction \( \text{CH}_3\text{OH} + \text{H}_2\text{O} \rightarrow \text{CO}_2 + 3\text{H}_2 \) can be regarded as the reversed methanol synthesis reaction. However, a detailed reaction mechanism is still under debate (5,6,7). In a kinetic model by Peppley et al. it is assumed that different active phases are responsible for the methanol decomposition, methanol-steam reforming, and the water-gas shift reaction (8).

The Cu/ZnO system has been studied extensively after reduction and under working conditions of methanol synthesis (9,10,11 and cited references therein). However, the active Cu phase for methanol reforming is not fully elucidated yet. Previously, differences in the reduction kinetics of CuO/ZnO were mainly studied by conventional temperature programmed reduction (TPR) methods (12,13). However, these methods do not measure the structural evolution of the catalyst during reduction (e. g. evolution of different bulk phases). Fierro et. al. studied the reduction of CuO/ZnO with different Cu/Zn ratios and found a
promoting effect of ZnO on the reducibility of CuO (14). The reduction kinetics of copper oxide were determined by thermogravimetric methods (15,16) which afforded sigmoidal curves indicating a nucleation growth mechanism. Structural investigations of the copper phase under reduction conditions based on XRD have been reported by Himelfarb et al. (17) and Vong et al. (18). Himelfarb et al. and Porta et al. (19) described an intermediary CuO phase, whereas this phase was not observed by Vong et al. However, the detection of CuO is based on ex situ investigations which may not represent the "real" state of the Cu phase under reduction conditions. Als-Nielsen et al. reported on an in situ detection of CuO by time-resolved QEXAFS without further analyzing the growth kinetics of this phase (20). Reitz et al. (21) observed Cu⁺ as a transient species in the reduction of CuO/ZnO catalysts by time-resolved XANES. Fernández-García et al. reported on the basis of a statistical analysis of TPR data of Cu/Al₂O₃ that the reduction process of copper aluminate proceeds via a two step mechanism (22).

Regarding the active state of Cu/ZnO catalysts, different authors claim that the ratio of Cu/Cu²⁺ governs the methanol conversion (24). This interpretation is closely related to the model of the active Cu/ZnO phase in methanol synthesis developed by Klier (25). Peppley et al. on the basis of a surface mechanism for methanol steam reforming proposed in a recent publication that the nature of the active sites differs according to their function (8), but no structural details are provided. The effects of preparation condition of precursors for Cu/ZnO catalysts upon precursors phases, surface structure and catalytic activity for steam reforming of methanol has been investigated by Shen et. al. (26).

In this study we used two complementary bulk techniques, in situ X-ray diffraction and X-ray absorption spectroscopy to elucidate bulk structural changes of Cu in Cu/ZnO systems during activation and under methanol steam reforming conditions. First, the evolution of bulk phases during activation of the catalyst (i.e. reduction in hydrogen with ('wet') and without ('dry') additional water vapor) was investigated. Secondly, correlations between the bulk structure of Cu on ZnO and activity or selectivity in the steam reforming of methanol are presented.

### Experimental Procedure

**CuO/ZnO preparation and characterization**

CuO/ZnO precursors were prepared according to the coprecipitation method, both at a constant pH of 7.0 and with decreasing pH, from metal nitrate and sodium carbonate solutions. Binary hydroxycarbonate precursors of a systematic series with varying Cu/Zn molar ratios were obtained and are denoted in the following according to their nominal Cu/Zn atomic ratio (100/0, 90/10, 80/20, 70/30, 60/40, 50/50, 40/60, 30/70, 20/80, 10/90, 0/100).

#### Table 1  Chemical composition and characterization of calcined CuO/ZnO precursors and reduced Cu/ZnO . Calcination conditions: 600 K for 3 h in stagnant air. Onset of reduction during TPR and the corresponding copper crystallites sizes after reduction are measured by in situ XRD. The reduction was performed under both 'dry' and 'wet' reducing conditions.

*Cu/Zn ratio determined by X-ray absorption, calculated using the Scherrer equation for CuO (111) and ZnO (100), not determined because of poor crystallinity, reproduced in 3 measurements, determined at the end of the TPR run at 523 K, reduction performed in ~ 2 vol-% H₂, reduction performed in ~ 2.5 vol-% H₂ and 3 vol-% H₂O.
Calcination of the hydroxycarbonate precursors at 600 K for 3 h in a muffle furnace in air afforded mixed CuO/ZnO systems. More preparative details are given elsewhere (27).

Specific surface areas were calculated by applying the BET method to the nitrogen isotherms obtained at liquid nitrogen temperature on samples outgassed at 423 K using a Quanitasorp Jr. (QuantaChrome) adsorption instrument. The sample nomenclature including the pH of the preparation and characterization of the calcined precursor with respect to CuO and ZnO crystallite size and the BET surface area is given in Table 1.

**In situ XRD**

The in situ XRD experiments were conducted using a STOE STADIP P diffractometer (Cu Kα radiation) in the Bragg Brentano scattering geometry equipped with a secondary monochromator and a scintillation counter operated in the stepping mode. The in situ cell consisted of a Bühlner HKD S1 high temperature diffraction chamber mounted onto the goniometer (28). In addition to a gas feed system for He, O₂, and H₂ as described in ref. (28), H₂O and MeOH were introduced by saturation of He with the respective liquids. Typically, 12 mg of the catalyst sample were used. Prior to any experiment the reactor was purged with He. Reduction of the precursors was performed in situ following a temperature program and in either 2 vol-% H₂ (denoted in the following as ‘dry’ reduction) or in 2.5 vol-% H₂O₂ and 3 vol-% H₂O₂ (+‘wet’ reduction) both in a He-flow of 100 ml/min. During precursor reduction and at temperatures between 433 K and 523 K an XRD pattern was recorded every 5 K at a constant temperature while applying a temperature ramp between every measurement resulting in an effective temperature ramp of 0.5 K/min. Thus, the uncertainty in on-set temperatures of reduction is 5 K. For the measurements during temperature programmed reduction a counting time of 2 s/step and a step width of 0.04° 2θ programmed reduction and simulation were performed using the software PowderCell v2.2 (30).

The full width at half maximum (FWHM) and integrated intensity of XRD-lines were determined by fitting pseudo Voigt (fixed Gaussian contribution) and Lorentz profile functions (more appropriate for strongly broadened profiles) to the Cu (111) peak. The Scherrer formula was used to estimate the crystallite size on the basis of the FWHM without taking other broadening effects and correction for instrumental broadening into account (29). Calculation of theoretical X-ray powder patterns and lattice constant refinements were done using the software PowderCell v.2.2 (30).

**In situ X-ray absorption spectroscopy**

The in situ XAS experiments were performed at beam line X1 at the Hamburger Synchrotron Radiation Laboratory, HASYLAB, using a Si(111) double crystal monochromator. The storage ring was operated at 3.6 GeV with injection currents of 150 mA.

The in situ XAS experiments were carried out in the transmission mode in a flow-reactor at atmospheric pressures (31). CuO/ZnO-samples prepared according to both preparation methods were investigated (constant pH samples C70/30, C60/40, C40/60, C30/70, C10/90 and decreasing pH samples D70/30, D60/40, D40/60). The samples were mixed with boron nitride (mass ratio CuO/ZnO: BN = 1:6) and 45 mg of the mixture was pressed with a force of one ton into a 5 mm in diameter pellet. The absorption jump at the Cu K edge was ~1.5. XANES spectra were measured in the Quick-EXAFS mode with a time resolution of 15 s/spectrum (8959-9100 eV).

A calibrated mass spectrometer (QMS200 Pfeiffer) permitted a quantitative analysis of the gas phase during the experiments. In situ EXAFS spectra were measured after oxidation and re-reduction to reveal structural changes of the Cu and Zn phases present. Temperature programmed reduction (TPR) runs were performed with 2 vol-% H₂ (constant pH samples) and 8 vol-% H₂ (decreasing pH samples) from 448 – 523 K with a temperature ramp of 5 K/min.

**XANES and EXAFS data analysis**

The software WinXAS v2.0 (32) was used for an analysis of the time-resolved Cu K edge XANES data to reveal qualitative and quantitative information on the copper bulk phases under TPR and steam reforming conditions. Identification of the number of phases was achieved by principal component analysis (PCA) of the experimental XANES spectra. Reference spectra of these phases were then used in a least-square fitting procedure of the time-resolved spectra to determine the fraction of each phase present (33). For the extended absorption fine structure (EXAFS) analysis, a smooth atomic background, ?₀(κ), was obtained using cubic splines. The radial distribution function FT(κ)(k) was obtained by Fourier transforming the κ²-weighted experimental ²(k) function, multiplied by a Bessel window, into R space. EXAFS data analysis was carried out using theoretical backscattering phases and amplitudes calculated with the ab initio multiple-scattering code FEFF 7 (34). Single scattering and multiple scattering paths in the employed model structures were calculated up to 6 Å for Cu metal and up to 5 Å for ZnO with a lower limit of 2.0% in amplitude with respect to the strongest backscattering path. In addition to the Zn-O and Zn-Zn distances extra Zn-Cu shells were employed assuming Zn on Cu sites in fcc Cu metal. EXAFS fitting and simulation were performed using the standard EXAFS formula (k range from 2.0 to 13 Å⁻¹, R range 1.5 to 6.0 Å (35). Structural parameters that are determined by a least-squares EXAFS fit to experimental spectra are (i) one E₀ shift for all scattering paths in the Cu bulk structure, (ii) Debye-Waller factors for single-scattering paths, (iii) single scattering shell distances, Rᵢ, and (iv) a third cumulant (36) to account for slight deviations from a Gaussian pair distribution function. Coordination numbers (CN) were
kept constant in the refinement. This restriction was necessary to reduce the number of free running parameter \( (N_{\text{ind}}) \) to much less than the number of independent parameters \( (N_{\text{par}}) \) in the experimental data used. EXAFS refinements reported here were carried out in \( \text{R} \) space to fit the magnitude and imaginary part of a Fourier transformed \( k^2 \)-weighted experimental \( \Phi(k) \). More details about the XAFS fitting procedure employed can be found in reference (37).

In-situ methanol steam reforming activity

The catalytic activity of the \( \text{Cu/ZnO} \) samples for steam reforming of methanol was determined at atmospheric pressure and 523 K using saturators for methanol and water at room temperature. After temperature programmed reduction and cooling to 298 K, the binary \( \text{Cu/ZnO} \) samples were exposed to \( \text{MeOH/H}_2\text{O} \) vapor in a ratio of 4/1 (c(MeOH) \( \sim 6 \text{ vol}-\% \), c(H\(_2\text{O}) \sim 1.5 \text{ vol}-\%) diluted in He; total flow through the XRD cell was 120 ml/min, and through the XAS cell was 25 ml/min. Next, the temperature was increased from RT to 523 K at 20 K/min. Reactants and products (MeOH, H\(_2\), H\(_2\text{O} \), and CO) were quantitatively monitored with a mass spectrometer (time resolution 12 s per scan). In order to measure changes in the phase composition during oxidation and reduction cycles, oxygen was added to the feed at (523 K) while the reaction was progressing (22 vol-% O\(_2\) for intervals of 100 min \( \text{in situ} \) XRD) and 15 vol-% O\(_2\) for 10 min \( \text{in situ} \) XAS).

In the following, selectivity refers to CO\(_2\) instead of \( \text{H}_2 \) because reactions other than the desired steam reforming produce hydrogen as well (i.e. decomposition to carbon monoxide and hydrogen, and dehydrogenation to formaldehyde and hydrogen). In addition, the water-gas shift reaction may also produce hydrogen. An error is introduced by not differentiating the CO\(_2\) stemming from the water-gas shift reaction. However, this reaction occurs to a much smaller extent than the steam reforming reaction. In order to express the hydrogen production activity in terms of a turnover frequency (i.e. number of product molecules of hydrogen formed per surface atom Cu per second) the number of exposed Cu surface atoms must be estimated. The number of surface atoms was calculated for the Cu surface area using a mean surface atom density of 1.47 \times 10^{19} \text{ m}^{-2} (38). The copper surface area was determined using the XRD crystal size and assuming a spherical copper crystallite shape. The assumption of spherical copper particles is based on crystal size estimates from the Cu (200) peak for samples with high copper concentration (> 60 mol-% Cu) which yielded similar values as that derived from the Cu (111) peak. We have previously shown that the Cu surface area thus determined agrees well with the surface area based on chemical titration with N\(_2\text{O} \) (39).

Results

1) \textit{In situ} XRD

a) Reduction of the CuO/ZnO precursor

Structural changes of the CuO/ZnO system were monitored by \textit{in situ} XRD during temperature programmed reduction (TPR). The evolution of the intensity of the Cu (111) line afforded the onset and extent of reduction while the evolution of the crystallite size was obtained from the line width. In Fig. 1 the normalized H\(_2\) and H\(_2\text{O} \) MS signals are correlated to the intensity evolution of the Cu (111) peak during TPR of the sample D70/30 in the range from 433 K to 523 K in 2 vol-% hydrogen. It can be seen that the uptake of H\(_2\) coincides with the evolution of H\(_2\text{O} \). The increase in the intensity of the Cu (111) peak indicates the growth of Cu crystallites. Because Cu particles large enough to be detected by XRD need to form, the onset of the evolution of the Cu (111) line is delayed with respect to the hydrogen uptake and the evolution of water.

![Evolution of integrated intensity of the Cu (111) peak and normalized mass spectrometer signals of H\(_2\text{O} \) and H\(_2\) during TPR of CuO/ZnO sample (D70/30) in 2 vol-% hydrogen measured by \textit{in situ} XRD. Measuring time 7 min/scan with an effective temperature ramp of 0.5 K/min.](www.fhi-berlin.mpg.de/ac)

Results of the TPR of all samples are summarized in Table 1. In most cases the onset temperature of ‘wet’ reduction was about 10 K higher than the onset temperature of ‘dry’ reduction. For the constant \( \text{pH} \) preparation and ‘wet’ reduction conditions decreasing copper content leads to a lower onset of reduction temperature; from 468 K (pure CuO, sample C100/0) to 448 K (sample C40/60), with sample C80/20 being an exception to this trend. For the decreasing \( \text{pH} \) samples a similar trend of decreasing onset temperature with decreasing Cu content is apparent for both ‘dry’ and ‘wet’ reduction conditions with sample D50/50 under ‘wet’ reduction conditions being an exception to this trend. No similar trend is apparent for the samples from the constant \( \text{pH} \) preparation under ‘dry’ reduction conditions. In addition, in most cases, ‘wet’ reduction leads to an increase in Cu crystallite size with
respect to that of ‘dry’ reduction (average increase ~ 4 Å). With increasing Zn content the Cu/ZnO samples exhibited a decreasing Cu crystallite size. The exceptions to the trend of decreasing Cu particle size with increasing Zn content are the 60/40 samples.

The evolution of the Cu crystallite size during TPR is shown in Fig. 2 as a function of the temperature. The Cu crystallite size appears to increase linearly with time (applying an effective temperature ramp of 0.5 K/min). For samples with lower Cu-concentrations the difference in crystallite size for ‘wet’ and ‘dry’ reduced samples is much less pronounced than for Cu-rich samples.

The characteristics of the catalytic activity of Cu/ZnO catalysts obtained from both preparation batches and reduction procedures (‘dry’ and ‘wet’) are summarized in Table 2. Highest conversion (38%) is obtained for the ‘wet’ reduced sample D70/30, whereas the ‘wet’ reduced copper rich sample D100/0 exhibits the lowest conversion. Similarly, the selectivity shows a strong dependence on the composition and reduction conditions and ranges from 79% (‘wet’ C60/40) to 16% (‘dry’ C90/10). The ‘wet’ reduced samples C60/40, C50/50, C40/60, and D60/40, D50/50, D40/60 show the same sequence in selectivity i.e. $^{5}\text{CO}_2$, $^{60}/40 > ^{50}/50 > ^{40}/60$ with similar absolute values (see Table 2). While selectivity to CO$_2$ is a function of conversion for all samples, at the same level of conversion the ‘wet’ reduced samples exhibit an enhanced selectivity compared to that of the ‘dry’ reduced samples. Selectivities of the ‘dry’ reduced samples are between 10 and 40% lower than those of the ‘wet’ reduced samples. Highest selectivities to CO$_2$ of ~ 80% at ~ 20% conversion are obtained for the ‘wet’ reduced samples C70/30 and C60/40 (see Table 2).

The in situ XRD investigations allowed calculation of the Cu crystallite sizes of operating catalysts which can be used to estimate copper surface areas. Hence, it is possible to detect influences of the Cu crystallite size (and metal surface area) on the activity without transferring the sample for ex situ measurements.

The Cu crystallite sizes measured during the steam reforming of methanol, and determined from the Cu (111) line width, are presented in Table 2. It can be seen by comparison with the crystallite sizes presented in Table 1, measured at the end of the precursor reduction, that during reaction the crystallite sizes increase. Furthermore, the same relationship of decreasing crystallite sizes with decreasing Cu content is obtained; however, in some cases the initially larger ‘wet’ reduced crystallites do not increase in size as much as the ‘dry’ reduced samples and so during reaction exhibit a smaller crystallite size (e.g. samples C80/20, C60/40, C70/30) than the ‘dry’ reduced samples.

The initial turn-over-frequency (TOF) for hydrogen production as a function of ZnO-content for catalysts prepared according to the decreasing or the constant pH method (both under ‘dry’ and ‘wet’ reduction conditions). Reaction conditions: MeOH/H$_2$O = 4/1, p= 101 kPa, total flow ~ 140 ml/min.
Table 2: Initial methanol steam reforming catalytic activity data (conversion of methanol, selectivity to CO₂, hydrogen production rate) and corresponding Cu crystallite size determined by in situ XRD. Reaction conditions: MeOH/H₂O = 4/1, p=101 kPa, total flow ~ 140 ml/min.

* calculated from the Cu crystallite size based on XRD data obtained during reaction  
** hydrogen molecules produced per surface copper atom per second  
* fast deactivation

It can be seen from Table 2 that the D-series samples exhibit a higher hydrogen production rate than the samples of the C-series. Furthermore, the samples prepared at constant pH show a greater variation in H₂ production rate than the D-series samples of similar Cu surface area.

The TOF for the initial activity as a function of ZnO-content in the catalysts is given in Fig. 3. The reaction rate is normalized to the number of Cu metal surface atoms. It can be seen that the TOF values vary with the catalyst composition having maximum values of 0.80 s⁻¹ for the ‘dry’ reduced Sample C60/40 and of 1.47 s⁻¹ for the ‘wet’ reduced Sample D60/40. In addition, samples prepared at decreasing pH show a higher TOF than the samples of the constant pH series. The differences in the TOF for ‘wet’ reduced samples as compared to that of those which underwent ‘dry’ reduction is small.

**Oxygen addition cycle**

In Fig. 4 four XRD patterns of a Cu/ZnO catalyst (sample C60/40) obtained after calcination (a), steam reforming (b), oxidation (c), and re-reduction (d) are displayed. The pattern indicative of CuO (a) is converted to that of metallic Cu (b) after the calcined sample is reduced in the steam reforming feed with no additional copper oxide phases detectable. The addition of 22 vol-% O₂ to the feed at 523 K for 100 min resulted in the formation of mostly Cu(I) oxide together with some minor amounts of Cu(II) oxide (c). After re-reduction in the feed at 523 K the XRD pattern of metallic Cu can be seen, but with a decreased line width of the Cu (111) peak (d). Changes in the product gas phase composition (H₂, MeOH, CO₂, and H₂O) during two oxygen addition cycles are depicted in Fig. 5. It can be seen that adding oxygen to the feed resulted in a complete loss of activity for the steam reforming reaction. In addition, the formation of water and CO₂ during the oxygen addition indicates the occurrence of total oxidation of methanol. The low hydrogen concentration observed during oxygen addition intervals might result from methanol dehydrogenation. The oxidative poisoning was, however, completely reversible with no loss in hydrogen productivity. Oxidation and re-reduction experiments were carried out on selected samples (C70/30, C60/40, C40/60) activated under ‘dry’ reduction conditions. The copper crystallite sizes, the methanol conversion, and selectivity are summarized in Table 3. An increase in conversion, selectivity, and hydrogen production rate with extending number of oxidation-reduction cycles is observed. In addition, the copper crystallite size expands with each oxidation cycle (Table 3).
Table 3 Change of catalytic activity data (conversion of methanol, selectivity to CO₂, hydrogen production rate) obtained in XRD and XAS cells after repeated oxidation and reduction steps. All samples were prepared according to the constant pH method and reduced at ‘dry’ conditions. The data was obtained at 523 K with a flow of MeOH/H₂O (ratio ~ 4/1) in 120 ml/min (XRD cell) or 25 ml/min (XAS cell) Conversion and selectivity are given as initial values.

| Sample name  | Number of oxidation/reduction cycles | Cu crystallite size [Å] | XRD cell | | XAS cell |  |
|--------------|-------------------------------------|-------------------------|----------|----------|----------|
|              |                                     |                         | XMeOH [%] | SCO₂ [%] | rH₂ [µmolH₂·g⁻¹·s⁻¹] |        |
|              |                                     |                         |          |          |                       |        |
| C70/30       | 0                                   | 76                      | 25       | 75       | 483                  | 25      | 54   | 145   |

d production rate of hydrogen per g catalyst and second cycle

For example, the copper crystallite size of the sample C70/30 increases from 76 to 110 Å and then to 120 Å. After the oxidation-reduction cycles the XRD peaks of ZnO (e.g. (100), (002)) are similarly affected in that their profiles become gradually more pronounced. Profile fitting of the ZnO (100) peak of C70/30 sample gives crystallite sizes that increase slightly upon oxidation and re-reduction from 80 to 90 Å. The relative changes of the copper and zinc oxide lattice parameter after reduction, under stream reforming conditions, and after successive oxygen/reduction cycles are depicted in Fig. 6.

Fig. 4 X-ray diffraction patterns of a sample with a composition of 60 at-% Cu and 40 at-% Zn (C60/40) during different stages of treatment. Upon reduction the calcined CuO (a) is transformed into Cu metal which is preserved under methanol steam reforming conditions at 523 K (b). Oxygen treatment resulted in a mixture of Cu(I) oxide and Cu(II) oxide (c). The oxidic copper phases are re-reduced in the feed to metallic Cu with a decreased line width (d). Characteristic (hkl) diffraction lines of CuO, Cu₂O, and Cu metal are indicated.

Fig. 5 Evolution of gas phase concentration of H₂, MeOH, CO₂, and H₂O in XRD cell under methanol steam reforming conditions during addition of oxygen (15 vol-% O₂) to the feed for two intervals of ~ 100 min. Sample C60/40 ‘dry’ was used. The change of Cu crystallite size is also indicated.
Fig. 6 Relative change of ZnO lattice parameters \(a\) and \(c\) (a) and Cu lattice parameter \(a\) (b) with respect to the values of the fresh reduced samples C70/30, C60/40, and C40/60 under methanol steam reforming, and after two successive oxygen addition cycles.

The continuous increase in lattice parameter of Cu and ZnO indicates an expansion of the unit cell under methanol steam reforming conditions after each oxidation/reduction steps with respect to the freshly reduced sample.

II.) In situ XAFS

a) Reduction of CuO/ZnO precursor

In situ X-ray absorption spectroscopy was performed at the Cu K edge to determine the evolution of the short-range structure of the less crystalline or amorphous copper phases which are not accessible by the in situ XRD measurements under reaction conditions. A principal component analysis of the Cu K edge XANES spectra revealed that three primary components were necessary to reconstruct the experimental XANES spectra. Using target transformation three probable reference compounds (i.e., Cu, Cu(I) oxide, Cu(II) oxide) were identified. In situ XRD results have shown that Cu in the oxide precursor was CuO and that it was completely reduced by TPR to Cu. The “target-transformed” spectra showed a good match with the first experimental XANES spectrum (containing only CuO) and the last spectrum (containing only Cu) in the TPR run. However, the result of the transformation for the third component showed considerable deviations from the experimental spectra of commercially available pure Cu2O. The poor match is probably due to the high crystallinity of the reference compound which may not reflect the local disorder (structural defects, decreased crystallinity and/or crystallite size) of the intermediately formed Cu(I) oxide. In order to account for the small crystallite sizes a reduction of the amplitude above the XANES edge of the experimental spectra resulted in an enhanced agreement with the transformed spectra. Hence, Cu(I) oxide is indeed an intermediate during TPR and the “target-transformed” spectrum was taken as a reference for Cu(I) oxide for the least square fits. The evolution of the phase composition during TPR of Sample D70/30 under ‘dry’ reduction conditions (2 vol-% H2 in 25 ml/min He, temperature ramp 448 K to 523 K at 5 K/min) is depicted in Fig. 7. It can be seen that the onset of reduction coincides with the evolution of H2O and the uptake of H2.

Fig. 7 Evolution of copper phase composition together with the MS signal of H2O (dotted) and H2 (solid) during TPR. The quantitative phase analysis is based on a least squares fit of Cu K edge XANES spectra of a CuO/ZnO sample (C70/30) during TPR in 8 vol-% H2 with 5 s/frame and a heating rate of 5 K/min using suitable reference spectra of Cu, Cu(I) oxide, and CuO as described in the text.

b) Steam reforming of methanol

In Fig. 8 the Cu K edge XANES spectra measured over a period of 20 min during oxygen addition to the feed at 523 K is presented. It can be seen that adding O2 to the feed (15 vol-%) results in an increase of the Cu K pre-edge feature. This corresponds to the oxidation of Cu to form Cu(I) oxide and Cu(II) oxide. The evolution of the concentration of MeOH, H2, H2O and CO2 together with traces of methylformate and CO (lower part of the graph) during two oxygen addition cycles are depicted in Fig. 9. It can be seen that after each oxygen and subsequent...
reduction cycle the resulting catalyst produces an increased hydrogen concentration as compared to that obtained after the initial reduction in 5% H₂. The catalytic performance after two oxidation/reduction cycles of a number of samples is given in Table 3.

![Absorption spectrum](image)

Fig. 8 Evolution of Cu K-edge XANES of CuO/ZnO at 523 K during oxygen addition to a methanol steam reforming feed (c(MeOH) ~ 6 vol-%, c(H₂O) ~ 1.5 vol-% in 25 ml/min He). Different Cu phases are indicated.

![Gas phase composition](image)

Fig. 9 Evolution of gas phase composition (H₂, MeOH, CO₂, and H₂O) during oxygen addition to a methanol steam reforming feed in the in situ XAFS cell. Concentration of CO and HCOOCH₃ is shown in the bottom part of the graph (sample C60/40).

The evolution of the copper bulk phases (i.e., formation of CuOₓₓ and re-reduction) and the corresponding gas phase composition during one oxygen addition to the feed is shown in Fig. 10. It can be seen that oxygen in the feed leads to a rapid oxidation of the copper particles to Cu(I) oxide and Cu(II) oxide (with a ratio of ~ 3/1). After the O₂ has been switched off the catalyst is re-reduced in the feed, the CO and H₂O concentrations decrease, and the H₂ concentration increases. Apparently, reversible changes of the oxidation state of copper can be observed during oxygen cycles due to oxidation and subsequent re-reduction processes in the feed (see Fig. 8). A catalytic activity similar to that before the oxidation is regained after 4 min. at which time only copper metal can be detected.

![XAFS refinement](image)

Fig. 11 Refinement of a sum of theoretical EXAFS function (dashed line) of Cu to an experimental FT(?)(k) of sample C70/30 at 523 K after reduction in 2 vol-% H₂. Only the four strongest single scattering EXAFS functions are indicated (thin dark lines). Fitted parameters are found in Table 4.

The extended fine structure (EXAFS) of the experimental XAFS spectra measured under reaction conditions at the Cu K and Zn K edges was investigated to analyze changes in the short-range order structure of Cu and ZnO during repeated oxidation and re-reduction cycles at 523 K during methanol steam reforming. In Fig. 11 a refinement of a theoretical Cu EXAFS function to an experimental Cu FT(?)(k) of sample C70/30 at 523 K under steam reforming conditions is depicted. Only the four most intense single
scattering paths in copper metal are displayed and a good agreement between experimental data and fit can be seen.

Table 4 Structural parameters of Cu/ZnO (C70/30) at 523 K under methanol steam reforming conditions (Fig. 11) obtained from a refinement of theoretical EXAFS functions calculated for Cu metal cluster (k = 2.0 to 13.0 Å⁻¹, R = 1.5 to 6.0 Å, N_{mol} = 32, N_{free} = 12, 5 single scattering paths and 14 multiple scattering paths). Parameters refined are E₀ (Cu) = 3.83 eV. The fit residual amounted to 2.8. Based on shells # 1, 2, 3, 5 an average lattice constant of a₀ = 3.6410 Å (Cu, Fm̅3m) was obtained.

The refined structural parameters are given in Table 4. During the fit the coordination numbers of Cu were kept constant to the values of bulk copper. This restriction is a reasonable assumption for the particle sizes investigated which have been shown by XRD to be larger than 80 Å. Therefore, size effects are assumed to play only a minor role in reduction of the amplitude in the FT(?) (40). Here the Debye-Waller (DW) factor is treated as a fitting parameter with coordination numbers fixed to those of the bulk metal. Hence, the Debye-Waller factor will be used to account for the apparent structural disorder in the copper crystallites and for the associated reduction in amplitude in the FT(?)

In the EXAFS analysis the Debye-Waller factors for the first, second, third, and fifth Cu-Cu shells are determined from a refinement of a theoretical EXAFS function to the experimental EXAFS functions of reduced binary samples measured at room temperature and at 523 K (shown in Fig. 12). For comparison, the DW factors obtained for a copper foil at room temperature are also given. It can be seen that the DW factors for the first three Cu-Cu shells for the samples at 523 K are higher than for those measured at room temperature. However, for samples C70/30 and C60/40 the DW factors of the fifth shell (5.7 Å) are about the same as those of the samples measured at room temperature. For samples C40/60 and C30/70 the DW factors are even lower at 523 K than at room temperature.

Fig. 12 Cu Debye-Waller (DW) Factors, ?², for the first, second, third, and fifth Cu-Cu distance obtained from a refinement of a theoretical EXAFS function to experimental data for reduced samples C70/30, C60/40, C40/60, C30/70 and Cu foil obtained at 303 K and 523 K under methanol steam reforming conditions.

The DW factors of the Cu foil are the lowest in all cases. After an oxidation addition cycle at 523 K the amplitude of the FT increases, indicating structural changes with respect to the fresh reduced catalyst. A smaller increase in FT(?)

Fig. 13 Cu Debye-Waller (DW) Factors, ?², for the first, second, third, and fifth Cu-Cu distance obtained from a refinement of a theoretical EXAFS function to experimental data for sample C70/30 (a) and C60/40 (b) obtained at 523 K during methanol steam reforming conditions after different pretreatment (fresh reduced) and after two subsequent oxidation and reduction steps (denoted as 1st O₂, SR and 2nd O₂, SR step).

The DW factors of the Cu foil are the lowest in all cases. After an oxidation addition cycle at 523 K the amplitude of the FT increases, indicating structural changes with respect to the fresh reduced catalyst. A smaller increase in FT(?)
is noted after the second oxidation cycle. The variation of the Cu DW factors for the first, second, third, and fifth Cu-Cu distance obtained from fitting experimental spectra of samples C70/30 and C60/40 obtained under working conditions at 523 K for different oxidative treatments is displayed in Fig.13a and b. An increasing Debye-Waller factor for the fifth Cu shell is detected for both samples after the second oxygen addition cycle. This effect seems to indicate an increasing medium range structural disorder in the copper particles with repeated oxygen addition cycles. Furthermore, changes in the local structural order of ZnO after oxidation/re-reduction cycles under reaction conditions were observed. In Fig. 14 the evolution of the experimental FT(\(\mathbf{r}(k)\)) of ZnO in sample C70/30 at 523 K during methanol steam reforming after initial reduction and after two oxidation/re-reduction cycles is depicted. A significant increase in amplitude of the FT(\(\mathbf{r}(k)\)) is clearly detectable with repeated \(\text{O}_2\)-addition cycles. Especially for the Zn-Zn distance at 2.8 Å a continuous increase can be seen. Higher shells also become more developed after repeated oxidation cycles. The observation of the increasing amplitude for both Cu and ZnO after oxidation and re-reduction implies that ZnO undergoes microstructural modification during oxidation/re-reduction cycles as well. To further elucidate the structural changes in the short-range order of ZnO after oxidation/re-reduction cycles, a refinement of theoretical EXAFS functions to the experimental spectra was performed.

As an example, Fig. 15 (a) shows the fit of a theoretical EXAFS function of ZnO to the experimental Zn K FT(\(\mathbf{r}(k)\)) of sample C70/30 under steam reforming reaction after different pretreatment (fresh reduced) and after two subsequent oxidation and reduction steps (denoted as 1st \(\text{O}_2\), SR and 2nd \(\text{O}_2\), SR step).

Fig. 14 Experimental Fourier transformed Zn K edge \(\mathbf{r}(k)\) (magnitude and imaginary part) of ZnO for sample C70/30 obtained at 523 K during methanol steam reforming after different oxidative treatments (fresh reduced) and after two subsequent oxidation and reduction steps (denoted as 1st \(\text{O}_2\), SR and 2nd \(\text{O}_2\), SR step).

This indicates that Zn in Cu clusters contributes significantly to the FT(\(\mathbf{r}(k)\)) of ZnO. By quantitative EXAFS-fitting of a sum of the two phases (ZnO + Zn in Cu) it is possible to determine the amount of Zn in the Cu clusters. For sample C70/30 the contribution to the total amplitude from scattering paths of Zn in Cu for the fresh reduced sample under reaction conditions amounts to ~10%. This amount diminishes to 5.1% after the first oxygen addition cycle and to 2.6% after the second cycle. By relating the contributions of scattering paths of Zn in Cu to the nominal Zn-content of the samples, the concentration of Zn in Cu can be estimated. For the fresh reduced sample C70/30 4.3 mol-% Zn was found to be dissolved in copper. After the first and second oxygen addition cycles the concentration of Zn in Cu was 2.2 and 1.1 mol-%, respectively. For the sample C60/40 an amount of 2.4 mol-% is dissolved in the Cu bulk of the fresh reduced sample.
and this was reduced to 1.3 mol-% and then 0.8 mol-% after oxygen addition cycles.

Discussion

1.) In situ XRD

Dependence of reducibility on catalyst composition

The presence of water retards the reduction onset temperature (~ 10 K) and results in higher Cu crystallite sizes (Fig. 2). Although the Cu/Zn ratio has only a slight effect on the onset temperature samples with increasing Zn content have smaller Cu particle sizes. The decreasing slope of the temperature-dependent Cu crystallite size with increasing Zn content seen in Fig. 2 indicates that ZnO exerts a stabilizing influence on the Cu particles during temperature programmed reduction. Fig. 2 (a) + (b) illustrate that during TPR the samples with the highest Zn-concentration (samples with C40/60 and D40/60) exhibit only minor crystallite growth with increasing temperature, whereas the Cu clusters in samples with a higher Cu-concentration tend to sinter more. Apparently, the tendency to sinter depends on the interaction with the ZnO-matrix and the Cu/Zn ratio. These results confirm previous investigations concerning the function of ZnO to keep the Cu crystallities in a dispersed state and thus maintaining a high surface area as previously described by Chinchen et al. (41) and Spencer (42). The exception to the previously mentioned trends are the samples with 60 mol-% Cu (C60/40 and D60/40) which show after reduction a Cu crystallite size that is 10 Å larger than that of the sample with 70 mol-% Cu (C70/30 and D70/30). The dependence of the reduction rate of CuO on the precursor composition is in good agreement with previous results by Porta et al. (19) and Himelfarb et al. (17) from an in situ XRD study. We have shown that for Zn concentrations larger than 40 mol-% the multiphasic composition of the hydroxy carbonate precursor shows a transition from the rosasite phase ((Cu,Zn)₂(OH)₃CO₃) to the aurichalcite phase ((Cu,Zn)₂(OH)₃(CO₃)₂) (27). The influence of the precursor structure which is apparently preserved in the calcined CuO/ZnO precursor can lead to an enhanced reduction rate due to the beneficial interaction of various types of defects leading to an increased reactivity of the solid phase. Those defects may be introduced during calcination of the hydroxy carbonate precursor at mild decomposition temperatures affording a high density of defects in the oxide. Our results support previous findings by Shen et al. (26) and Porta et al. (19) on the effect of hydroxy carbonate precursor phases on the reducibility and Cu crystallite size. Furthermore, the nucleation process influences the reduction rate and it can be imagined that the interaction of the Cu metal nucleus with ZnO can lead to differences in the growth in three dimensions (19). In most cases the addition of water in ‘wet’ reduction experiments caused a shift of the onset of reduction to higher temperatures (Table 1). The influence of water addition could be explained by both thermodynamic and kinetic effects. First, the water partial pressures employed for the ‘wet’ TPR (~ 30 mbar) experiments dilutes the hydrogen and results in an increased formation temperature of the Cu phase due to the reduced reduction potential (43). Second, the inhibition of the reduction by additional water according to the law of mass action can occur as well. Third, there may be a retarding influence of water on the formation of Cu nuclei. This kinetic explanation has been previously discussed by Wimmers et al. for a TPR study of Fe₂O₃ particles under ‘wet’ reduction conditions (44).

Effects of precursor preparation and reduction conditions on the catalytic performance

The influences of the Cu/Zn ratio and the reduction method on the selectivity in methanol steam reforming are discussed for both constant and decreasing pH sample preparation methods. Most samples exhibit an increasing selectivity with decreasing conversion. For instance, the selectivities of samples C50/50 and D50/50 increase from ~70% to ~80% while the conversion drops from 20 to 10%. The reduction procedure affects the catalytic selectivity more clearly than the pH during precipitation of the precursors. This dependence of the selectivity on the reduction conditions is in contrast to the TOF which seems to be unaffected by the reduction treatment of the samples. In addition, the elemental composition has a strong effect on the selectivity. An optimum composition in terms of selectivity is attained for a narrow range of 60 – 70 mol-% Cu for the constant pH samples. This investigation of the selectivity of binary catalysts in methanol steam reforming supplements previous studies on the catalytic performance for binary Cu/Zn catalysts with different Cu/Zn ratios (26,13). The most stable sample is C70/30 ‘wet’ as it shows only small variation in conversion and selectivity.

It is clear from Table 2 that there is no straightforward correlation of the production rate with the Cu surface area over the entire compositional range of the samples. In addition, it is found that although in most cases the ‘wet’ reduction mode results in a higher copper surface area an enhanced production rate is not observed for those samples (e. g. samples D40/60, D50/50, and C70/30). In addition, in all cases, the D-series samples exhibit a higher activity for a given copper surface area than the C-series samples.

In order to relate differences in performance of the catalyst to effects originating from preparation parameters, the composition, and the reduction conditions, the production rate is normalized to the Cu metal surface area estimated from the copper XRD crystallite size. The initial TOF for H₂ is a function of the ZnO-content (see Fig. 3). Comparing the TOF values (ranging from 0.2 to 1.3) to other studies which employ similar reaction conditions although with equimolar MeOH/H₂O ratio it is found that they are of the same order of magnitude (26,13). However, highest TOF values are reported by Shen et al. (26) for the pure copper sample whereas in our study the catalyst with 60 mol-% Cu exhibits the highest intrinsic activity irrespective of preparation or reduction conditions. The
TOF values for catalysts with ZnO-contents higher than 40 mol-% Zn do not show the nearly linear increase in TOF with increasing Zn content seen in the samples with less Zn. For concentration > 40 mol-% Zn the TOF is independent on the Cu surface area and the values do not differ much as a function of preparation and reduction mode. Furthermore, catalysts prepared at decreasing pH displayed a higher overall TOF than samples prepared at constant pH. This indicates that the precipitation pH affects the activity of the copper in the final catalyst. The influence of the pH during preparation is only seemingly in contrast to the behavior of the selectivity, which showed no dependence on the pH during preparation, because for the determination of the TOF for H\textsubscript{2} all reactions affording hydrogen were taken into account. In addition, ‘wet’ reduction leads to higher TOF-values for the decreasing pH sample batch whereas ‘dry’ reduced constant pH samples exhibit a slightly higher TOF-values. The significant deviations from a constant TOF as a function of the composition implies that the copper surface area alone cannot adequately account for the differences in intrinsic activity. The catalyst D60/40 is exceptional as the activity of a copper surface atom can be twice as high for a given elemental composition than that for the sample C60/40 indicating the influence of preparation parameters on the catalytic activity as a function of the pH during preparation (i.e. increased TOF) (Fig. 3).

The absence of a linear relationship between the copper surface area and the methanol-steam reforming activity provides additional evidence that the methanol steam reforming reaction is “structure sensitive”. This is in contrast to results by Shen et al. (26) who proposed that the production rate is associated with the surface of metallic Cu. A “structure-sensitivity” was reported by Hadden et al (45) for the water-gas shift reaction. They have shown that the specific activity is not directly correlated to the Cu metal surface area and concluded that preparation parameters determine to a large extent the activity for a given Cu surface area. In a recent publication by Peppley et al. a kinetic model for methanol-steam reforming is presented (6). It was found that the methanol steam reforming reaction and the methanol decomposition to CO and hydrogen proceed on different active sites, although the rate-determining step (dehydrogenation of absorbed methoxy groups) is the same in both cases. Furthermore, it was shown that the active site responsible for the methanol steam reforming reaction is similar to the one responsible for the water-gas-shift reaction. This type of sites is thought to be formed in situ and incorporates the presence of Cu\textsuperscript{2+} aggregates stabilized by hydroxyl and carbonate groups (46).

The present work indicates that an additional microstructural parameter different from the Cu surface area is operative. This becomes more apparent in the catalytic experiments after oxidation/re-reduction cycles. In situ XRD afforded an increase in crystallite size after oxygen addition cycle accompanied by an increase in conversion of methanol and selectivity to CO\textsubscript{2} (Table 3). The increase in crystallite size can reach up to ~90% (from 70 Å to 120 Å for the sample C70/30). The origin of this pronounced increase in Cu crystallite size after each oxidation cycle can be related to a structural rearrangement during oxidation and re-reduction (Fig. 4). Although the increase in Cu particle size results in a loss of Cu surface area, higher conversions and selectivities are observed (Table 3) after oxidation cycles. Combining the activity data for the oxidation cycles shown in Fig. 5 (sample C60/40) with the Cu crystallite size determined by in situ XRD an increase of the TOF as a function of oxidation cycle can be measured. After the first cycle the TOF increases from 1.1 to 1.5 and after the second cycle the TOF reaches 1.6 s\textsuperscript{-1}. Again, these observations are in contrast to the simplified correlation of the catalytic activity with the Cu surface area, and, hence, the crystallite size (26). A lattice parameter determination by in situ XRD yielded a continuous increase of the copper lattice parameter and the ZnO lattice parameters a and c under methanol steam reforming conditions and with each oxygen addition cycle (Fig. 6). The evolution of the lattice parameters may originate from the influence of the Cu/ZnO interface which may increase after each oxygen addition cycle, increasing the effect of the misfit of the two lattices (see below, XAS discussion). Using the Voigt method (47) it is found that in addition to size effects the broadening of the Cu (111) diffraction line is also caused by microstrain in the Cu bulk. For the sample D60/40 a Cu crystallite size of 90 Å was determined while the extent of strain amounted to 0.7%. After oxidative treatments and growth of the copper crystallites (increase in size to 102 Å) the strain contribution to the peak broadening (0.7%) was unchanged, indicating that there was no accompanying annealing of defects. Apparently, the re-oxidation experiments in the XRD cell show that a high Cu surface area is a prerequisite for an active CuZnO catalyst. However, additional microstructural parameters need to be considered to account for the activity and selectivity observed. Further evidence for bulk structural changes under reaction conditions were gained from the in-situ XAFS experiments.

II.) In situ XAFS

Activation of the CuO/ZnO catalysts - TPR

Time-resolved XANES experiments at the Cu K edge indicate that Cu(I) oxide is an intermediate of the reduction of the CuO/ZnO systems studied (Fig. 7 (a)). In addition, these experiments afforded the evolution of the three phases CuO, Cu, and Cu(I) oxide during temperature-programmed reduction of CuO/ZnO (Fig. 7) not accessible by conventional TPR studies. Previously, features in the TPR spectra of CuO/ZnO system were attributed to different degrees of dispersion of the CuO without taking possible intermediates during the reduction processes into account (12). Compared to in situ XRD results where the detection of copper metal requires a certain minimum crystallite size which in TPR causing a delay in the appearance of copper metal after detection of the evolution.
of water, in situ XAS can afford complementary information on the early stage of reduction. Apparently, the reducibility of the CuO/ZnO systems (Cu nuclei formation during reduction) depends not only on the Cu/Zn ratio in the catalyst as has been reported before (12) but also on the preparation conditions of the hydroxycarbonate precursor. This supports previous findings on the influence of the preparation method on the reduction process by Fierro et al. (14) and Himelfarb et al. (17).

Steam reforming of methanol

Time-resolved in situ XAFS measurement were performed to correlate different copper phases with catalytic activity during oxygen addition cycles to the methanol steam reforming feed (Fig. 8, Fig. 9). The changes in Cu phase composition and the evolution of the gas phase for one oxygen addition cycle are shown in Fig. 10. After the addition of oxygen, Cu(I) and Cu(II) oxide constitute the major copper bulk phases. In regime III (Fig. 10) copper metal is formed again and its formation is accompanied by an increasing hydrogen production but no CO or methyl formate is formed in this period. This could imply that the methanol dehydrogenation reaction is favored over Cu in a positive oxidation state. The formation of CO and methyl formate (ppm levels) originating from methanol steam reforming is observed only after the concentration of metallic copper in the bulk phase exceeds 80 w-% (regime III to I in Fig. 10). The maximum concentration of CO and methyl formate (1000 ppm) coincides with the complete reduction of the copper phases to Cu metal. Our observation of both methyl formate (HCOOCH₃) and CO in regime I (Fig. 10) supports the sequence of reaction steps involving dehydrogenation and methylformate formation. During subsequent methanol steam reforming, the CO level is continuously decreasing whereas the concentration of methyl formate remains constant. In this regime (I in Fig. 10) methanol steam reforming appears to be the predominant reaction. It can be concluded that the changes of bulk phase and gaseous product composition observed during oxygen addition cycles permit one to distinguish between different active states of copper operative in the Cu/ZnO system. The results support previous assumption based on kinetic analysis of surface reactions that parallel reaction might occur on different active copper phases during methanol-steam reforming (8.6). Interestingly, the oxidation and reduction curves of Cu metal in the upper graph in Fig. 10 exhibit in both cases a sigmoidal shape for both solid state processes indicating similar rate determining steps and reaction rates.

Implication of microstructural changes of Cu and ZnO on the catalytic activity

The existence of copper suboxides in the bulk during methanol steam reforming can be excluded within the detection limits of XAFS (~1 w-%) in the XANES region. Furthermore, for the Cu edge EXAFS no Cu-O shells were distinguishable after applying the difference file technique. Nevertheless, the formation of mixed valence copper suboxides at the catalysts surface cannot be excluded. Surface oxygen atoms on copper (under methanol oxidation conditions) which are different from oxygen in well-defined copper oxides have recently been reported by Knop-Gericke et al. using surface sensitive in situ XAS (48,49).

In recent publications (50, 51) the dynamics of the CuZnO system were ascribed to changes in the morphology of the Cu surface. Clausen et al. (50) observed using EXAFS dynamical changes of the system upon changing the reduction potential in the gaseous environment and ascribed them to changes in the surface morphology (wetting/non-wetting phenomena). They showed that by taking changes in surface area and morphology (i.e. formation of Cu(110) and Cu(100) surfaces with higher activity) into account a "dynamic" microkinetic model for the methanol synthesis reaction under different gas atmospheres could be deduced. Sakakini et al. (51) reported on surface morphology changes of a supported Cu/ZnO/Al₂O₃ catalyst using IR spectra of adsorbed CO. The copper surface termination and the activity for CO₂ decomposition showed a dependence on the reductive treatment after previous oxidation.

In the work presented here microstructural changes of Cu and ZnO upon oxygen addition cycles are correlated to methanol steam reforming activity. The EXAFS refinements to the experimental Cu and ZnO ?(k) gave ample evidence of the bulk structural interaction of both phases leading to the following structural changes (Fig.11, Fig. 15). The unusual high Debye-Waller factor of the fifth copper shell indicates a medium range structural disorder of the Cu/ZnO at room temperature (Fig.12). This structural disorder may be caused by interaction at the Cu/ZnO interface assuming an expansion of the Cu lattice at the interface. An epitaxial orientation of the Cu (111) surface to the ZnO (001) surface has been found to exist in the Cu/ZnO system (52). Upon increasing the temperature to 523 K the copper lattice will expand more than the ZnO lattice because of the difference in the linear thermal expansion coefficients, of Cu (53) and ZnO (perpendicular to the c-axis): of Cu, 500 K = 17.4·10⁻⁶ K⁻¹ and ZnO = 71.5·10⁻⁶ K⁻¹ (54). At elevated temperature the thermal expansion of Cu results in a partial release of the lattice mismatch at the interface and, thus, in a reduction of structural disorder as indicated by the decreased or constant DW factors of the fifth Cu shell (Fig. 12).

In situ EXAFS measurements during oxygen addition cycles under methanol steam reforming conditions gave further evidence of microstructural changes in the Cu/ZnO samples (Fig. 14). The Cu Debye-Waller factors indicated that the medium range disorder for copper particles increased with each oxidation/re-reduction cycle (see Fig. 13) while the copper crystallite size as detected by XRD increases after each oxygen addition cycle. After oxidation/re-reduction cycles the increase in medium range
disorder is accompanied by a depletion of Zn incorporated in the Cu clusters (Fig. 14 and Fig. 15) (~ 4.3 mol-% for sample C70/30 to 1.3 mol-% after two cycles). The observed lattice expansion of < 0.02 Å (Fig. 6) is below the limits for a reliable distance determination by EXAFS. The Zn atoms dissolved in Cu stem from the structural arrangement in the hydroxycarbonate precursor structure and maintain their position in the Cu-matrix under the mild calcination (600 K) and reduction conditions (5 vol-% H₂ at 523 K) used (39). Apparently, the amount of Zn dissolved in the copper clusters depends not only on the Cu/Zn ratio of the catalyst but also on the structure of the hydroxycarbonate precursor as indicated by the lower Zn-concentration for Cu in the more Zn-rich C60/40 sample as compared to the C70/30 sample. The incorporation of Zn in Cu can be regarded as a modification of the copper surface leading to a modified reactivity as previously discussed by Nakamura et al. (55) for Cu/ZnO catalysts in methanol synthesis.

Moreover, substantial incorporation of Cu into the ZnO matrix (> 1%) for Zn-rich catalysts as found by Klier et al. (56) can be excluded on the basis of their EXAFS results.

Taking this experimental evidence into account it seems reasonable to assume that the enhanced activity after oxidative treatment for methanol steam reforming is closely related to disorder and strain in Cu particles in an analogous manner as it was found for Cu/ZnO catalysts in methanol synthesis. Regarding the role of defects in copper we have recently reported (39) on the implication of the Cu lattice strain of copper clusters in the crystallite size regime 50 – 200 Å on the methanol synthesis activity. It is suggested that the microstrain modifies the Cu surface and thus contributes to an enhanced methanol synthesis activity (39). The structural defects of Cu were ascribed to the dissolution of Zn in Cu, incomplete reduction or epitaxial orientation of Cu and ZnO. This concept seems to be transferable to the active copper phase in the methanol steam reforming reaction. Modified Cu surfaces were found to have a promotional effect on the methanol synthesis activity and it appears from our data that for methanol steam reforming a similar structural disorder of the copper bulk also results in a higher activity and selectivity. This is clearly shown by the increase of the TOF after each oxidation cycle indicating a more active copper surface.

Model of microstructural changes of Cu and ZnO

The microstructural modifications detected by XAFS and XRD during oxygen addition cycles under working conditions can be summarized by the schematic model given in Fig. 16. The model depicts the structural rearrangement of Cu on ZnO for a freshly reduced catalyst (a) and a more active catalyst (b) after oxidation and subsequent reduction. For the freshly reduced catalyst the small copper particles are in interfacial contact with the supporting ZnO, possibly exhibiting an epitaxial orientation. The Cu crystallite size is only slightly lower than that of ZnO and the copper particles exhibit some structural disorder which may be caused by microstrain originating at the Cu/ZnO interface. Furthermore, a considerable amount of Zn (up to 4.3 mol-%) is incorporated into the Cu clusters, occupying Cu lattice sites and forming a solid solution of Zn in Cu. After oxidation and subsequent reduction (Fig. 23b) the crystallite sizes of Cu and ZnO increase, resulting in a reduced surface area which may also be accompanied by an increased interface area between Cu and ZnO. With the observed growth in crystallite size there is a decrease in the concentration of Zn in the Cu, and an increase in structural disorder in the Cu particles as indicated by the increasing Cu Debye-Waller factors for higher Cu-Cu shells. The partial segregation of Zn atoms out of the Cu lattice seems to increase interface interaction between Cu and ZnO. It is speculated that the Zn atoms incorporated in the Cu particles diminishes the effect of the Cu/ZnO interface on the copper particles and, therefore, the microstrain is not transmitted across the entire copper matrix, and does not modify the copper surface. Hence, after oxidation and re-reduction larger domains of distorted and strained copper are formed on the ZnO support. Much more than an inert support, ZnO appears to be a crucial component in modifying the microstructure (e.g. interface interaction, Zn incorporation in Cu particles), and thus the activity of the copper.

Fig. 16 Proposed schematic model for copper particles on a ZnO support after initial reduction (a) and after repeated oxygen addition cycles under methanol steam reforming conditions (b). The microstructural modifications upon oxidative treatment result in an increasing crystallite size and a larger interface area between Cu and ZnO. Moreover, the Cu clusters are depleted of Zn accompanied with larger domains of structural disorder (e.g. strain) in Cu (parallel lines).

With respect to model systems for nanosized Cu/ZnO catalysts, in light of our findings, a suitable model system needs to account for the strong support influence of ZnO on Cu and for Zn incorporated in the copper bulk.

Conclusion

Evolution of bulk phases of Cu/ZnO catalysts under reduction conditions was monitored by in situ XRD and XAFS revealing the following:

(a1) From time-resolved in situ XAFS experiments at the Cu K edge, Cu(I) oxide was found to be an intermediate of the reduction of CuO/ZnO according to a two step reduction process (CuO \( \neq \) Cu(I) oxide \( \neq \) Cu).

(a2) CuO/ZnO precursors which were less easily reduced (high reduction onset temperature) afforded Cu crystallites that are more selective in steam
reforming of methanol. The use of ‘wet’ reduction conditions, also resulting in a shift to higher onset of reduction temperatures, also produces catalysts exhibiting a higher selectivity.

Structural and catalytic properties were monitored during methanol steam reforming reaction by in situ XRD and XAFS and the following conclusions were drawn:

(b1) Completely reduced Cu clusters on ZnO constitute the active bulk phase for methanol steam reforming with no further oxidized Cu species detectable (<1%).

(b2) Upon repeated oxygen addition cycles, the catalyst exhibited an enhanced activity (i.e. increased TOF) and selectivity. It was shown by XRD and EXAFS that repeated oxygen addition cycles lead to a crystallite growth of both the copper and zinc oxide crystallites accompanied by a segregation of Zn out of the Cu bulk. However, the Debye-Waller factors for higher Cu-Cu shells suggest an increasing structural disorder (e.g. strain). The strain is thought to originate at the Cu/ZnO interface.

(b3) ZnO is not just a support but an integral part of the active Cu/ZnO catalyst. The bulk structure and, hence, the catalytically active surface is modified by the intimate Cu/ZnO interface.

(b4) The microstructural changes of copper and zinc correlate with increased methanol steam reforming activity and selectivity. This indicates that although a high Cu surface area is a prerequisite for catalytic activity it does not account for the observed changes in activity and selectivity alone without taking bulk structural changes into account. We conclude that similar to methanol synthesis the enhanced activity in Cu/ZnO catalysts after oxidative treatment for methanol steam reforming is closely related to an increased disorder and microstrain in Cu particles.

In this study it was shown that for “real” Cu/ZnO catalysts solid state transformation and interaction of the Cu and ZnO phases have a pronounced influence on the catalytic activity. Therefore, “ideal” Cu clusters fail to describe the structural imperfections observed and, hence, cannot be expected to be suitable model systems. Apparently, a suitable model system needs to account for both strong Cu/ZnO interface interactions and Zn incorporated in the copper bulk.
